EUROPEAN PATENT SPECIFICATION

Post-reception focusing in remote detection systems

Ferndetektionssysteme mit Nachempfangsfokussierung

Systèmes de détection à distance à focalisation de post-réception

Note: Within nine months from the publication of the mention of the grant of the European patent, any person may give notice to the European Patent Office of opposition to the European patent granted. Notice of opposition shall be filed in a written reasoned statement. It shall not be deemed to have been filed until the opposition fee has been paid. (Art. 99(1) European Patent Convention.)
The present invention relates to a method and apparatus for detecting a potential reflector and the use of said apparatus in a radar system, in a ground penetrating radar system for mine detection or in a medical imaging system. Remote detection systems, such as radar systems, scan a beam of energy through a predetermined search space in order to locate objects therein. Many radar systems still perform this scanning by the physical rotation of a radar dish. However, phased array radar systems perform beam steering by simultaneously powering a plurality of transmit elements for each direction of look. The signals supplied to the transmit elements are collectively shifted in phase so that the individual signals constructively interfere along a chosen path and destructively interfere along other paths. Thus, the phase and optionally the power of the signals supplied simultaneously to each of the elements must be controlled separately for each direction of look or in the case of near field focusing for each focal resolution cell examined.

0002 GB 2034554 A discloses holographic imaging using electromagnetic waves. An array of antenna comprises linear transmitter antenna interleaved with receiver antenna. The array is mechanically focused to produce a narrow vertical beam. A signal processor, including a beam former, computes the I' and Q' components of the phase differences of the received signals.

0003 US 5177445A discloses a method of detecting non-metallic materials by a recognition of the way in which their electrical properties vary with the frequency of an applied alternating field. The pattern of variation of a body's reflection at different frequencies is evaluated and compared with stored information.

0004 US 5339080A relates to an earth-penetrating image radar. A plurality of frequency synthesizers are used within a single frequency generator to transmit a fast-stepped synthetic image.

0005 According to a first aspect of the present invention, there is provided an apparatus for detecting a reflector located within a volume of a medium, the apparatus comprising a transmitter, a transmit array consisting of a plurality of transmit elements, a receiver, at least one receive element, and processing means for processing signals received by the at least one receive element, characterised in that: the transmit array extends in two dimensions and the transmit elements of the transmit array are energised one at a time so as to transmit a signal into the volume of the medium; reflected signals received by the at least one receive element are recorded; and the processing means processes the recorded signals to bring signals propagated from at least two of the transmitting elements via a selected potential reflector location within the volume into coincidence by shifting them thereby synthesising focusing of the signals on the selected potential reflector location.

0006 The processing of the received signals can be repeated in respect of all desired reflector locations.

0007 Thus, the applicants have realised that it is possible to significantly reduce the cost, complexity and power requirements in the transmitter portion of a detection system at the expense of increased post reception computation.

0008 The reflector may be an object located within the medium, a discontinuity within the medium or an inhomogeneous region within the medium.

0009 It is thus possible to provide an apparatus in which the reflectivity or a plurality of cells within a search volume are investigated, and the reflected radiation is analyzed in order to determine whether one or more of the cells contains a reflector.

0010 Preferably, a plurality of receiving elements are provided in an array. The signals received by each of the receiving elements can be further processed by the introduction of appropriate phase or time shifts between the received signals to focus or beam steer the response of the receiving array of elements.

0011 In general, there may be T transmission elements and R receiving elements. Each of the T elements is actuated in turn and the data received by each of the R receiving elements are recorded or stored. The data is processed so as to bring the TxR signals from each transmit element via a chosen potential reflector location to each receive element, into time and phase coincidence, just as if the transmit and receive arrays had been focused onto a given point in space. Equivalent processing operations can be performed for all 3D cells resolvable within the intrinsic constraints of the antenna and modulation systems. Thus, a single actuation of each transmit element can take the place of separate actuations for all distinct joint focusing conditions of the transmit and receive arrays.

0012 The elements of the transmit and receive arrays may be provided within a single physical array with each element of the array being selectively connected to a transmitter or a receiver.

0013 This arrangement will be herein referred to as a monostatic mode of operation. Alternatively, dedicated transmit and dedicated receive elements may be provided. These form electrically discrete arrays, although physically the arrays need not be discrete. These arrangements will be referred to as bistatic systems.

0014 Advantageously, the receive signals are recorded and stored in digitised form. The recording period is required to span that time period (echo time) starting with a return signal from the nearest desirable target range, and finishing with a signal returning from the furthest target range. The phase and advantageously the amplitude of the returning signals are recorded.

0015 The energy may be in the form of electro-magnetic radiation. Radio frequency radiation falling within the microwave or millimetre region of the electro-magnetic spectrum are preferred radiation. Alternatively acoustic waves,
such as ultra-sound, may be used.

[0016] The detection system may be incorporated within a radar system to detect remote objects. Alternatively, the system may be incorporated within a near-field radar system, or near-field acoustic ranging system, in order to detect discontinuities or objects within a medium. Examples of such systems are ground penetrating radar systems for mine detection, or medical diagnostic systems for non-invasive imaging.

[0017] The terms "near field" and "far field" are understood by the person skilled in the art. However, by way of explanation, known phased array antennas used in radar systems of the type used to detect aircraft perform beam steering and consequently are intended to produce a beam having a substantially planar wavefront. The plane wave front eventually diverges at an angle which decreases with increasing size of the initial plane aperture. The orientation of this planar wave front steers it in two dimensions (e.g. azimuth and elevation) and its planar nature focuses it to infinity. Any convex curved wavefront would generate a more widely diverging beam, and a concave wavefront would converge onto a focal point and diverge from there onwards. This initial convergence onto a "near-field" focal point is exploited in the present invention. Quite generally, the near field describes the region near the antenna where the wavefront shape is relatively complex and is still evolving towards the narrow divergent beam that is observed in the far field.

[0018] Preferably the frequency of the electro-magnetic radiation or acoustic wave is adjustable so as to set the wavelength thereof in the medium to a predetermined wavelength. The speed of propagation of electromagnetic or acoustic radiation depends on the physical nature of the propagating medium. Since the resolution achieved is a function of the wavelength in the medium, the use of a variable frequency electromagnetic wave or acoustic wave source allows the resolution to be controlled. In, for example, a ground penetrating radar system constituting an embodiment of the present invention, the wavelength of the microwaves in moist soil is between 1/3 and 1/8 of the free space wavelength. If the frequency of operation is kept constant, these changes in wavelength would affect the attenuation in the course of ground penetration and the focusing resolution of the apparatus. By controlling the frequency of operation, it is possible to maintain the wavelength in the medium at a substantially constant value, thus maintaining a substantially constant resolution and minimising changes in attenuation. The characteristics of the medium (e.g. attenuation and propagation speed) may, for example, be determined by transmitting signals of at least one frequency (and normally two or more frequencies) between two sensor probes in contact with the medium and measuring the phase shift and/or attenuation (or changes thereof) between the transmitted and received signals. Alternatively these measurements may be performed by back scatter measurement techniques.

[0019] Preferably impedance matching means is provided intermediate the or each antenna or the plurality of transmitting elements and the at least one receiving element and the medium. In embodiments employing electro-magnetic radiation as an interrogating signal, the or each antenna may be faced with a compliant sheet matching the observed characteristics of the medium. The electrical matching of the antenna elements with the medium substantially prevents energy being reflected back to the transmitter. The sheet may be in contact with the medium thereby providing effective continuity of the bulk impedance between the antenna and the medium. Alternatively, the index matching sheet may be spaced from the medium such that reflections from the sheet (for example, from the face nearest the sheet) and from the surface of the medium undergo destructive interference and substantially cancel one another.

[0020] The storage or recording processing generates a time-bracket of signals from each transmit element via the propagation medium to each receive element. Synthetic focusing comprises selecting from each of these brackets that sample whose path delay is consistent with having passed from the given transmit element to the given receive element via the selected focal cell, and summing all these contributions in a phase coherent manner. However, in near-field focusing, there is likely to be a wide variation in the two-way path-length from that for the transmit and receive element pair closest to the selected focal cell to that for the element pair furthest away. Since the medium is likely to be lossy, and attenuation increases exponentially with path length, this results in an even wider variations of signal contributions from pair to pair. But effective focusing requires substantially equal contributions from all components. Hence the signals from the shorter two-way paths are preferably attenuated to match those from the longer paths.

[0021] A co-pending application published as EP0 812 028 A having the same priority date and applicant as the present application describes searching for buried mines by means of a radar, near-field focusing onto all relevant resolution cells in turn within a search volume. A specific example is described, where each of two triplets of disc antennas searches a volume of 1m x 1.5m x 0.6m with 5cm 3D resolution, by focusing sequentially onto all 7200 resolution cells so defined. The transmit antennas are multielement arrays which are focused using the principles of mutual interference between a plurality of transmitted signals. This results in many transmissions into the same volume, each restricted to examining a single voxel.

[0022] With the phased array type spot-focused operation, each of 7200 transmissions involves exciting all elements of the transmitting antenna. In the basic form of the present invention the aggregate power transmitted is reduced 7200-fold, for the same performance, by using all transmissions from all antenna elements to contribute in full to the examination of all 7200 resolution cells, as follows:-

[0023] Each operation of focusing onto one resolution cell involves the coherent alignment of the signals from all
relevant transmitting antenna elements via the selected focal cell to all relevant receiving antenna elements. Consider the bistatic case. If the elements of the transmitting array are energised one at a time, the amplitudes and phases of the corresponding received signals can be recorded concurrently for all elements of the receiving array, at all relevant path delays. This process is repeated for all the transmit-array elements. The signals for each, or selected, cells can then be analyzed. For each 3D cell, the path delays from each transmit-antenna element via that cell to each receive-antenna element are calculated or looked up and used to extract the corresponding signal from the stored data. These contributions can then be scaled in power, for loss normalisation, and further weighted for any taper, for side-lobe reduction, associated with the relevant transmit and/or receive antenna element. Since these scaling and weighting operations are applied to the detected received signal, they scale signal and noise alike (unlike transmitter weighting, which degrades this signal/noise ratio).

In a monostatic implementation, each of the N elements of the array has to transmit in turn. At first sight, it would appear that it is necessary to record the signals received in all the N-1 other elements. However, for full information, it is sufficient to record the signals received in half of these elements: half the two-way paths will be observed with element i transmitting and element j receiving, and half with j transmitting and i receiving, where i and j represent selected ones of the N elements (i, j ≤ N). However, all elements must be used both for transmitting and receiving, since we cannot observe a path between two transmit-only elements or two receive-only elements. Note that for concurrent focusing, for each distinct 3D resolution cell, we have to control the phases of N transmit paths plus (if bistatic) N receive paths. Each with a phase tolerance of δ (where δ is, say, 10°). This contrasts with synthetic focusing, where we have to control N(N-1)/2 two-way paths per resolution cell (if bistatic N² paths) with a tolerance of ±2δ. (In near-field focusing, unlike synthetic apertures in radio astronomy, equally-spaced pairs of elements do not share a common path delay.) Thus we pay the price of (N(N-1)/2)-fold (or N-fold) increased processing for the dramatic saving in transmitter power.

Where the same N antenna elements are used in a monostatic operation, the transmit sequence may be visualised by regarding the elements as being positioned around the circumference of a circle, where the reception of the signal is limited to the N/2 elements immediately behind the current transmitting elements. When all of the transmitting elements have been actuated once, this ensues that each of N(N-1)/2 paths between distinct pairs of elements is observed once.

Advantageously, the arrays of antenna elements may be moveable so as to conform to the surface profile of a medium. Sensors may be provided to measure the vertical displacement, roll and pitch of the antenna array or arrays in order that the position of each element in the or each array can be calculated and further corrections to the phase or travel time of the signals made so as to accurately perform the post reception focusing.

Advantageously, the transmitted signals are in the form of pulses. In an example of a ground penetrating radar system, microwave pulses possibly of the order of nanosecond duration are transmitted. Alternatively, a continuous wave signal can be frequency modulated in a linear manner (chirped) typically over a range of order of GHz or less (the frequency domain equivalent of the time domain pulse). The technical difficulties of pulse forming or frequency modulation are reduced in the case of an acoustic detection system due to the slower propagation speed of the interrogating energy.

Each discriminable received pulse, corresponding to a single transmitted pulse, will be the resultant of the reflections from all inhomogeneities within the volume defined by:-

1. the directional pattern of the transmitting element (or sub-array),
2. the directional pattern of the receiving element (or sub-array),
3. the leading edge of the received pulse,
4. the trailing edge of the received pulse.

Preferably, each receive signal is correlated with the transmitted signal. This enables the correct arrival time of the receive signal to be established. The results of the correlations can be recorded for subsequent processing.

The transmit and receive antennas may be mounted on a boom for use in a mine detection system. The boom may be mounted on a vehicle.

The system can also be used for medical diagnosis. Growths or tumours frequently have a different metabolism to the surrounding tissue and frequently have a different impedance thereto. Thus the growths or tumours will reflect microwaves or ultra-sound and consequently can be located using this technique.

Each transmitter element may be actuated more than once. This allows the number of correlators to be reduced since they can be time shared. This does, however, reduce the overall power saving, although the reduction in peak transmitted power (since the elements are still actuated sequentially) remains unchanged. Additionally, the relative
sizes of the transmit and receive arrays can be adjusted to increase the number of transmit elements and decrease the number of receive elements. This again allows the number correlators to be reduced.

According to a second aspect of the present invention, there is provided a method of detecting a remote reflector, comprising the steps of: sequentially actuating individual transmit elements (18) of a two dimensional transmit array to transmit respective signals into a medium under investigation; receiving signals reflected from the medium under investigation using at least one receive element and recording the signals; and processing the recorded or stored signals to bring signals propagated from at least two of the transmitting elements via a selected potential reflector location within the volume into coincidence by shifting them thereby synthesising focussing of the signals on the selected potential reflector location.

The present invention will further be described, by way of example, with reference to the accompanying drawings, in which:

Figure 1 illustrates the loci of the leading edge of a received pulse and trailing edge of a received pulse for a bistatic system; and

Figure 2 schematically illustrates an embodiment of the present invention.

For a bistatic configuration, leading edge 2 and trailing edge 4, i.e. the loci of constant two-way path length of a pulse, are ellipsoids of revolution, with the relevant transmit 6 and receive 8 elements as their foci. (Thus they reduce to constant-range spheres in a monostatic system). The N^2 pairings of transmit and receive elements generate N^2 such zones, differing in lateral position and curvature, and these overlap and combine coherently only in the selected resolution cell, whose size is determined by the wavelength and the pulse-length, and by the focusing and bistatic convergence angles. Exactly the same selection mechanism is in operation (in a less obvious manner) in conventional quasi-optical focusing.

In a ground penetrating radar system (schematically illustrated in Figure 2) transmit and receive arrays 10 and 12 have 150 elements each, and are positioned such that the difference between the longest and shortest likely two-way 3D path lengths is approximately 3m. In the arrangement shown in Figure 2, a transmitter 16 is selectively connectable to each one of the plurality of transmitter elements 18 within the transmit array 10. Alternatively, independent transmitters may be activated sequentially.

Each of the antenna elements 20 of the receive array 12 are connected to a respective receiver 22 which includes a data storage device, and a correlator 24. Only one receiver and correlator block is shown for clarity. The correlator 24 acts to cross-correlate the signal received from the antenna element 20 with the transmitted signal. The outputs of all of the receivers are sent to a data processor 26 which analyses the received signals in order to determine whether or not an object, such as a mine is located in the volume of any of the search cells within the ground 28. Hence, for a 5cm resolution inphase "I" and quadrature "Q" correlators 24, associated with each receive element, have to be sampled up to 60 times for each transmit-element activation. Hence, in data collection the scheme, in its basic form, would need perform 18000 correlations: 150 (arrays elements) x 60 (discriminable phase intervals) x 2 ("I" and "Q" phases) = 18000. In processing these data, we have to compute the sum of 150 x 150 = 22500 complex contributions per focal cell, for each of a total of 7200 resolution cells. This comes to a total of 7.24 x 10^8 additions. Typically, the mechanical limitations of a contact search would impose a minimum time of 6 seconds to advance the search area 1.5m forward, for the next search scan, corresponding to a computation rate of 1.2 x 10^7 additions, which is a fairly trivial task.

In a contact mine search system, a sensor on a boom ahead of the search vehicle, may have to be preceded by a non-ferrous cutting and clearance tool on a further forward extension of the sensor boom. Since the ground will normally be rough, good contact may require the front-face of the antenna arrays to be faced with a soft mat of the appropriate index-matching material. For such contact, it is necessary to place the antenna onto the ground and take a series of measurements, and then lift the antenna and move it to the next, adjacent ground position. The ground is also likely to be uneven on a larger scale. A T-shaped boom projects forward from the operating vehicle, far enough to ensure the safety of the vehicle in an accidental mine explosion. Antenna arrays are mounted at a front-end cross-piece of this boom. Each of these arrays can adapt to the gross variations of the ground, both vertically and by tilting about the roll and pitch axes, with sensors measuring these displacements, so that the excitation can be adapted accordingly.

With in-contact arrays, an ultra-sonic acoustic version of the apparatus can also be implemented. This would perform best in wet ground, the very conditions where a microwave system is most limited. The echoing delay times would of course be enormously larger than in the electro-magnetic variant. However, as shown below (for the electromagnetic scheme), any in-contact scheme the search rate is limited entirely - and quite severely - by non-sensor considerations.

The data acquisition time is merely the time for each of say 150 transmit elements in turn to emit a single
pulse and then to wait for the largest relevant path delay to the receivers before the next element emits its pulse. With either the electro-magnetic or ultra-sonic version of the invention, that time is negligible compared to the mechanical processes of manipulating the antenna or transducer array in contact with the ground. Hence the computation for the synthetically focused 3D search can also be spread over the time taken by these mechanical processes.

For instance, a cyclic search scheme may be as follows:

<table>
<thead>
<tr>
<th>Step</th>
<th>Description</th>
<th>Duration</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>fit discs to ground</td>
<td>3s</td>
</tr>
<tr>
<td>2.</td>
<td>sequential beam forming and search</td>
<td>-</td>
</tr>
<tr>
<td>3.</td>
<td>advance boom by 1.5m (vehicle remaining stationary)</td>
<td>6s</td>
</tr>
<tr>
<td>4.</td>
<td>repeat 1 - 3</td>
<td>9s</td>
</tr>
<tr>
<td>5.</td>
<td>repeat 1 - 3</td>
<td>9s</td>
</tr>
<tr>
<td>6.</td>
<td>repeat 1 - 2</td>
<td>3s</td>
</tr>
<tr>
<td>7.</td>
<td>advance vehicle 6m, whilst retracting boom by 4.5m</td>
<td>15s</td>
</tr>
<tr>
<td></td>
<td><strong>TOTAL DURATION</strong></td>
<td><strong>45s</strong></td>
</tr>
</tbody>
</table>

Subsequent cycles would repeat steps 1 - 7, above. This scheme is designed to minimise the time taken by the mechanical processes, which dominate the search rate. These arbitrary but not unrealistic figures give a total of 45s for searching 2m (width) x 6m (advance) x 0.6m (depth), - i.e. an average advance of 1m every 7.5 seconds.

The highest time resolution will be required for the lowest refractive index. The refractive index \( P \) of ground varies between 3 and 8, when \( P = 3 \). For a path-delay resolution of 5cm, this will then correspond to a time resolution of 0.5 nanoseconds, equivalent to a bandwidth of 2GHz. If "simple" pulse operation and direct phase sampling in such a short interval proves too expensive in terms of components with very few cycles per pulse, equivalent results can be obtained by means of a linear frequency modulation (chirp) of \( \pm 1 \)GHz, with an appropriately carrier frequency. The received signal has to be correlated (in I and Q) with a distinct delayed replicas of the transmitted waveform for each discrete resolvable pathlength. In this case, however, each correlator is occupied for the full duration of the chirp sweep, thus requiring a bank of parallel correlators for each receive-antenna array. The magnitudes of the resulting correlation integrals can, once again, be recorded digitally. With longer pulses the same range resolution can be retained through convergence focusing, but it is then subject to range coordinate side lobes.

It is possible to drive each transmit element \( k \) times, so that \( 1/k \) the number of receive correlators can be time-shared, at the expense of a \( k \)-fold reduction in the power saving achieved. The number of receive correlators could be reduced by yet further factor, again at the cost of a proportionate increase in the total transmitted power, by increasing the size of the transmit antenna 10 and reducing that of the receive antenna 12, by a common ratio, thus keeping the number of path-length combinations constant. Both the preceding measures increase the data-collection time. However, in no circumstances does the electronic observation time impose any constraints on the system design. Yet a further savings measure (which however does not affect the data-collection time) is to divide the angular range covered by the receive antennas into, subarrays of, say, 3 by 3 elements. Since the solid angle of these subarray beams would be 9 times narrower than the single-element beam, the subarrays, jointly have to be phase-steered into 9 angular sub-ranges. Fine steering, within each subrange, can be performed by differential phasing ("squinting") of the sub-arrays. Thus each receive element requires phase-steering to 9 discrete directions, and hence each transmit element has to be driven 9 separate times, reducing the power saving accordingly. On the other hand, for each of the subarray look angles, only the composite output of each receive sub-array would need to be correlated with each transmit signal. Hence the number of correlators is reduced 9-fold (each being used 9 times, once for each sub-array squint angle).

In the non-contact mode of operation, the range-wise (i.e. distance along travel path) dimension of volume to be searched electronically, using the data from the 150 x 150 path combinations, would be reduced from 150cm (30 voxels) possibly to 30cm (6 voxels) i.e. one disc diameter, but probably to 1 voxel. This would however have to be repeated for every 30cm or 5cm of advance of a vehicle incorporating the detection system, respectively. The number of \( (i,j) \) pairs to be covered would of course be unchanged. However, the difference between the maximum and minimum 2-way path delays to be covered would be reduced to only about 90cm, as compared to 3m, thus permitting a pro rata reduction in the number of correlators. Here, too, the electronic search rate will not limit the overall search rate achievable. The transmitted and returning wavefronts may undergo refraction at the air-ground interface. However corrections for this can be made based on measurements or assumptions of the propagation speed within the ground.

Since the components of a focused spot are obtained sequentially, the technique (in all its variants) is best suited to observing static situations as in mine search (or tumour diagnosis). However, specific hypotheses of target movement can also be covered.

Synthetic focusing can also be applied to far-field radars. In that case, the previous range-dependent 3D beam focusing is reduced to range-independent 2D beam forming and steering. Hence the number of incremental delays required is drastically reduced, and indeed these delays can be implemented as phase shifts, if desired. Range
is then resolved purely by arrival time, and the data recorded at each receive antenna element must cover the full 
ecoing time to maximum range. Since the number of independent beams, which can be formed in a phased array, is 
equal to the number of elements, the data collection time, with sequential transmission from all antenna elements in 
turn, is the same as for a conventional phased array performing a sequential search of all distinct beam directions. 
However, the transmitted power is much reduced. Like the phased array, the synthetically-focused system can save 
both search-time and processing, when searching a more restricted angular range. For synthetic beam forming, this 
could be achieved by configuring the transmit and receive antennas as sets of sub-arrays, with their (common) 
beamwidth and “squint” angle matched to the desired angular coverage.

Because such synthetic beam forming depends on the coherent combination of data collected sequentially, 
it is best matched to scenarios which can be regarded as static during the data-collection frame, but where we wish 
to observe frame-to-frame changes - with appropriate inter-frame intervals. This condition would be less restrictive in 
single-dimensional synthetic beam forming and steering: For instance, for a vertical receiver-synthesised scan, 20 
horizontal lines of transmit elements, within a 300-element circular transmit array, might be energised sequentially, and 
so the minimum target coherence time required would be reduced in the ratio 20/300 = 1/15. Thus there should be 
further applications where, for instance, vertical synthetic beam forming and steering would be combined with rotational, 
translational or phased-array scanning in the horizontal plane.

Claims

1. An apparatus for detecting a potential reflector located within a volume of a medium (28), the apparatus comprising 
a transmitter (16), a transmit array (10) consisting of a plurality of transmit elements (18), a receiver (22), at least 
one receive element (20), and processing means (24, 26) for processing signals received by the at least one 
receive element, characterised in that: the transmit array extends in two dimensions and the transmit elements 
(18) of the transmit array are energised one at a time so as to transmit a signal into the volume of the medium; 
reflected signals received by the at least one receive element (20) are recorded; and the processing means proc-
esses the recorded signals to bring signals propagated from at least two of the transmitting elements via a selected 
potential reflector location within the volume into coincidence by shifting them thereby synthesising focussing of 
the signals on the selected potential reflector location.

2. An apparatus as claimed in claim 1, in which a plurality of receiving elements are provided in an array (12).

3. An apparatus as claimed in claim 2, in which the signals received by each of the receiving elements (20) can be 
further processed by the processing means (26) by the introduction of appropriate phase or time shifts between 
the received signals to synthesise near-field focusing or far-field beam steering of the response of the receiving 
array of elements.

4. An apparatus as claimed in any one of the preceding claims, in which there are T transmission elements, and R 
reception elements, and in which each of the transmission elements is actuated in turn and data received by each 
of the reception elements are recorded or stored, and in which the data are processed by the processing means 
(26) to bring the T x R signals from each transmit element (18) via a chosen potential reflector location to each 
receive element into time and phase coherence.

5. An apparatus as claimed in any one of the preceding claims in which the transmit and receive elements are provided 
within a single physical array with each element being selectively coupled to a transmitter (Tx) or a receiver (Rx).

6. An apparatus as claimed in any one of claims 1 to 4, and comprising dedicated arrays (10, 12) of transmit and 
receive elements.

7. An apparatus as claimed in any one of the preceding claims in which the received signals are recorded during a 
recording period starting with a signal returned from the nearest desirable target range and finishing with a signal 
returning from the furthest target range.

8. An apparatus as claimed in claim 7 , in which the phases of the returning signals are recorded.

9. An apparatus as claimed in claim 7 or 8, in which the received signals are recorded and stored in a digitised form.

10. An apparatus as claimed in any one of the preceding claims, in which the transmitting elements (18) emit electro-
magnetic radiation or acoustic waves.

11. An apparatus as claimed in claim 10, in which the electromagnetic radiation is microwave or millimetre wave radiation.

12. An apparatus as claimed in claim 10 or 11, in which the frequency of the electromagnetic radiation or acoustic wave is adjustable as to set the wavelength thereof in the medium (28) to a predetermined wavelength.

13. An apparatus as claimed in claim 10, 11, or 12, in which the propagation characteristics of the medium are measured by back scatter or by transmitting signals of at least one frequency between at least two sensor probes and measuring the phase shift between the transmitted and received signals.

14. An apparatus as claimed in any one of the preceding claims, in which the transmitting elements and the at least one receiving element form at least one antenna (10, 12), and impedance matching is provided intermediate the or each antenna and the medium.

15. An apparatus as claimed in claim 14, in which the or each antenna is faced with a sheet matching the characteristics of the medium.

16. An apparatus as claimed in claim 15, in which the sheet is compliant so as to permit operation in close contact with a rough surface.

17. An apparatus as claimed in claim 14, in which the or each antenna is associated with an index matching sheet spaced from the medium such that reflections from the sheet and from a surface of the medium undergo destructive interference.

18. An apparatus as claimed in any one of the preceding claims, further comprising means for attenuating signals having short two-way path lengths to match those from longer paths.

19. An apparatus as claimed in claim 5 or 6, in which the or each array of antenna elements are moveable so as to conform to the surface profile of the medium.

20. An apparatus as claimed in claim 19, in which sensors are provided to measure the vertical displacement, roll and pitch of the or each array in order that the position of each element in the array can be calculated and further corrections made to the phase or travel time of the received signals so as to perform post reception focusing.

21. An apparatus as claimed in any one of the preceding claims, in which the transmitted signals are in the form of pulses.

22. An apparatus as claimed in any one of claims 1 to 20 in which the transmitted signals are frequency modulated.

23. An apparatus as claimed in any one of the preceding claims, in which each received signal is correlated with the transmitted signal.

24. An apparatus as claimed in any one of the preceding claims, in which the received signals are correlated with the transmitted signals and in which each transmitter element is actuated more than once.

25. An apparatus as claimed in any one of claims 1 to 23 in which, in use, the elements of the transmitting array are energised one at a time, the amplitudes and phases of the receiving array are recorded concurrently for all elements of the receiving array and all relevant path delays, then for each cell the path delay from each transmit element via the cell to each receive element are used to extract the corresponding signal from the stored data, the signals are then scaled in power and summed.

26. A radar system comprising an apparatus as claimed in any one of the preceding claims.

27. A ground penetrating radar system for mine detection, comprising an apparatus as claimed in any one of claims 1 to 25.
28. A medical imaging system comprising an apparatus as claimed in any one of claims 1 to 25.

29. A method of detecting a potential reflector, comprising the steps of:
   actuating individual transmit elements (18) of a two dimensional transmit array one at a time to transmit respective signals into a medium under investigation;
   receiving signals reflected from the medium under investigation using at least one receive element and recording the signals;
   and processing the recorded or stored signals to bring signals propagated from at least two of the transmitting elements via a selected potential reflector location within the volume into coincidence by shifting them thereby synthesising focussing of the signals on the selected potential reflector location.

30. A method of detecting a remote reflector as claimed in claim 29 in which the recorded signals are shifted so as to synthesise in the received signals the delays and phase shifts that would have been introduced between the transmit elements in the transmit array in order to steer or focus the transmitted energy using phase array techniques.

Patentansprüche

1. Vorrichtung zur Feststellung eines möglichen Reflektors, der innerhalb eines Volumens eines Mediums (28) angeordnet ist, umfassend einen Sender (16), eine Senderanordnung (10) bestehend aus mehreren Sendeelementen (18), einen Empfänger (22), wenigstens ein Empfangselement (20) und eine Verarbeitungseinrichtung (24, 26) zur Verarbeitung von Signalen, die durch wenigstens ein Empfangselement empfangen werden, dadurch gekennzeichnet, dass sich die Sendeordnung in zwei Dimensionen erstreckt und die Sendeelemente (18) der Sendeordnung jeweils nacheinander erregt werden, um ein Signal in das Volumen des Mediums zu senden; dass die durch das wenigstens eine Empfangselement (20) empfangenen Signale aufgezeichnet werden; und dass die Verarbeitungseinrichtung die aufgezeichneten Signale verarbeitet, um die Signale, die sich von wenigstens 2 Sendeelementen über einen ausgewählten möglichen Reflektorort innerhalb des Volumens fortpflanzen, in Übereinstimmung zu bringen, in dem sie verschoben werden, um hierdurch die Fokussierung der Signale auf den ausgewählten möglichen Reflektorort synthetisch herzustellen.

2. Vorrichtung wie in Anspruch 1 beansprucht, bei welchem mehrere Empfangselemente in einer Anordnung (12) vorgesehen sind.

3. Vorrichtung wie in Anspruch 2 beansprucht, bei welchem die durch jedes der Empfangselemente (20) empfangenen Signale durch die Verarbeitungseinrichtung (26) weiterverarbeitet werden können durch die Einführung von geeigneten Phasen- oder Zeitverschiebungen zwischen den empfangenen Signalen, um eine Nahfeld-Fokussierung oder eine Fernfeld-Strahlsteuerung der Antwort des empfangenden Feldes von Elementen synthetisch herzustellen.

4. Vorrichtung wie in irgendeinem der vorangehenden Ansprüche beansprucht, bei welchem es T Sendeelemente und R Empfangselemente gibt und bei welchem jedes der Sendeelemente der Reihe nach betätigt wird und durch jedes der Empfangselemente empfangene Daten aufgezeichnet oder gespeichert werden und bei welchem die Daten durch die Verarbeitungseinrichtung (26) verarbeitet werden, um die T x R-Signale von jedem Sendeelement (18) über einen ausgewählten möglichen Reflektorort zu jedem Empfangselement in Zeit- und Phasen-Kohärenz zu bringen.

5. Vorrichtung wie in irgendeinem der vorangehenden Ansprüche beansprucht, bei welchem die Sendee- und Empfangs-Elemente innerhalb eines einzigen physikalischen Feldes vorgesehen sind, wobei jedes Element selektiv an einen Sender (Tx) oder einen Empfänger (Rx) angekoppelt ist.

6. Vorrichtung wie in irgendeinem der Ansprüche 1 bis 4 beansprucht und zugewidmete Anordnungen (10, 12) von Sendee- und EmpfangsElementen umfassen.

7. Vorrichtung wie in irgendeinem der vorangehenden Ansprüche beansprucht, bei welchem die empfangenen Signale während einer Aufzeichnungsperiode aufgezeichnet werden, beginnend mit einem Signal, das von dem nahesten wünschenswerten Zeltbereich zurückgeführt wird und endend mit einem Signal, das von dem entfer-
8. Vorrichtung wie in Anspruch 7 beansprucht, bei welchem die Phasen der zurückgeführten Signale aufgezeichnet werden.

9. Vorrichtung wie in Anspruch 7 oder 8 beansprucht, bei welchem die empfangenen Signale in einer digitalisierten Form aufgezeichnet und gespeichert werden.

10. Vorrichtung wie in irgendeinem der vorangehenden Ansprüche beansprucht, bei welchem die Sendeelemente (18) elektromagnetische Strahlung oder akustische Wellen aussenden.

11. Vorrichtung wie in Anspruch 10 beansprucht, bei welchem die elektromagnetische Strahlung eine Mikrowellen- oder Millimeterwellen-Strahlung ist.

12. Vorrichtung wie in Anspruch 10 oder 11 beansprucht, bei welchem die Frequenz der elektromagnetischen Strahlung der akustischen Welle einstellbar ist, um die Wellenlänge derselben in dem Medium (28) auf eine vorgestellte Wellenlänge einzustellen.

14. Vorrichtung wie in irgendeinem der vorangehenden Ansprüche beansprucht, bei welcher die Sendeelemente und das wenigstens eine Empfangselemente wenigstens eine Antenne (10, 12) bilden und eine Impedanzanpassung zwischen der oder jeder Antenne und dem Medium vorgesehen ist.

15. Vorrichtung wie in Anspruch 14 beansprucht, bei welcher die oder jede Antenne mit einer Platte abgedeckt ist, die an die Charakteristik des Mediums angepasst ist.

16. Vorrichtung wie in Anspruch 15 beansprucht, bei welchem die oder jede Antenne abgedeckt ist, um einen Betrieb in engem Kontakt mit einer rauen Oberfläche zu gestatten.

17. Vorrichtung wie in Anspruch 14 beansprucht, bei welcher der oder jede Antenne eine Index-Anpassplatte im Abstand von dem Medium zugeordnet ist, so dass Reflektionen von der Platte und von einer Oberfläche des Mediums eine zerstörende Überlagerung erfahren.

18. Vorrichtung wie in irgendeinem der vorangehenden Ansprüche beansprucht, ferner umfassend Mittel zur Dämpfung von Signalen, die kurze Zweiweg-Weglängen besitzen, um jene an längere Wege anzupassen.

19. Vorrichtung wie in Anspruch 5 oder 6 beansprucht, bei welchem die oder jede Anordnung von Antennen-Elementen beweglich ist, um sie an das Oberflächenprofil des Mediums anzupassen.

21. Vorrichtung wie in irgendeinem der vorangehenden Ansprüche beansprucht, bei welchem die gesendeten Signale in der Form von Impulsen vorliegen.

22. Vorrichtung wie in irgendeinem der Ansprüche 1 bis 20 beansprucht, bei welchem die gesendeten Signale frequenzmoduliert sind.

23. Vorrichtung wie in irgendeinem der vorangehenden Ansprüche beansprucht, bei welchem jedes empfangene Signal zu dem gesendeten Signal korreliert ist.

24. Vorrichtung wie in irgendeinem der vorangehenden Ansprüche beansprucht, bei welchem die empfangenen Si-
gnale zu den gesendeten Signalen korreliert sind und bei welchem jedes Sendeelement mehr als einmal betätigt wird.

25. Vorrichtung wie in irgendeinem der Ansprüche 1 bis 23 beansprucht, bei welchem in der Verwendung die Elemente der Sendeordnung nacheinander erregt werden, die Amplituden und Phasen der Empfangsanordnung gleichzeitig für alle Elemente der Empfangsanordnung und alle relevanten Wegverzögerungen aufgezeichnet werden, sodann für jede Zelle die Wegverzögerung von jedem Sendelement über die Zelle zu jedem Empfangselement verwendet wird, um das entsprechende Signal aus den gespeicherten Daten herauszuziehen und die Signale sodann in der Leistung skaliert und summiert werden.

26. Radarsystem umfassend eine Vorrichtung wie in irgendeinem der vorangehenden Ansprüche beansprucht.

27. Erdurchdringungs-Radarsystem zur Minenfeststellung, umfassend eine Vorrichtung, wie sie in irgendeinem der Ansprüche 1 bis 25 beansprucht ist.

28. Medizinisches Abbildungssystem umfassend eine Vorrichtung, wie sie in irgendeinem der Ansprüche 1 bis 25 beansprucht ist.

29. Verfahren zur Feststellung eines möglichen Reflektors, umfassend die Schritte:

- Betätigung einzelner Sendeelemente (18) einer zweidimensionalen Sendeordnung nacheinander, um entsprechende Signale in ein zu prüfendes Medium zu senden;

- Empfang der von dem Medium unter Prüfung reflektierten Signale unter Verwendung wenigstens eines Empfangselementes und Aufzeichnung der Signale;

- und Verarbeitung der aufgezeichneten oder gespeicherten Signale, um die Signale, die sich von wenigstens zwei Sendeelementen über einen ausgewählten möglichen Reflektorort innerhalb des Volumens fortspiegeln, in Übereinstimmung zu bringen, in dem sie verschoben werden, um hierdurch die Fokussierung der Signale auf den ausgewählten möglichen Reflektorort synthetisch herzustellen.

30. Verfahren zur Feststellung eines möglichen Reflektors wie in Anspruch 29 beansprucht, bei welchem die aufgezeichneten Signale verschoben werden, um in den empfangenen Signalen die Verzögerungen und Phasen-Verschiebungen zu ermitteln, die zwischen den Sendeelementen in der Sendeordnung eingeführt worden sind, um die gesendete Energie unter Verwendung von Phasen-Anordnungstechniken zu steuern oder zu fokussieren.

Revidiierungen

1. Appareil destiné à détecter un réflecteur de potentiel situé dans un volume d'un support (28), l'appareil comprenant un émetteur (16), une matrice d'émission (10) constituée d'une pluralité d'éléments d'émission (18), un récepteur (22), au moins un élément de réception (20) et un moyen de traitement (24, 26) destiné à traiter des signaux reçus par ledit au moins un élément de réception, caractérisé en ce que : la matrice d'émission s'étend dans deux dimensions et les éléments d'émission (18) de la matrice d'émission sont actionnés un par un afin d'émettre un signal dans le volume du support ; des signaux réfléchis reçus par ledit au moins un élément de réception (20) sont enregistrés ; et le moyen de traitement traite les signaux enregistrés pour amener en coïncidence les signaux qui se propagent à partir d'au moins deux desdits éléments d'émission, via un emplacement de réflecteur de potentiel sélectionné dans le volume, en les décalant, ce qui entraîne la synthèse de la focalisation des signaux sur l'emplacement du réflecteur de potentiel sélectionné.

2. Appareil selon la revendication 1, dans lequel une pluralité d'éléments de réception est organisée en matrice (12).

3. Appareil selon la revendication 2, dans lequel les signaux reçus par chacun des éléments de réception (20) peuvent être en outre traités par le moyen de traitement (26) en introduisant une phase ou des décalages temporels appropriés entre les signaux reçus pour effectuer la synthèse de la focalisation en champ proche ou le pilotage de faisceau en champ lointain de la réponse de la matrice de réception des éléments.

4. Appareil selon l'une quelconque des revendications précédentes, dans lequel se trouvent Τ éléments d'émission
et R éléments de réception, et dans lequel chacun des éléments d'émission est actionné à son tour et des données reçues par chacun des éléments de réception sont enregistrées ou stockées, et dans lequel les données sont traitées par le moyen de traitement (26) pour amener les T x R signaux depuis chacun des éléments d'émission (18), via un emplacement de réflecteur de potentiel choisi, vers chacun des éléments de réception en cohérence de temps et de phase.

5. Appareil selon l'une quelconque des revendications précédentes, dans lequel les éléments d'émission et de réception sont placés dans une matrice physique unique, chacun des éléments étant sélectivement couplé à un émetteur (Tx) ou à un récepteur (Rx).

6. Appareil selon l'une quelconque des revendications 1 à 4, comprenant des matrices dédiées (10, 12) d'éléments d'émission et de réception.

7. Appareil selon l'une quelconque des revendications précédentes, dans lequel les signaux reçus sont enregistrés pendant une période d'enregistrement commençant par un signal renvoyé à partir de la portée cible la plus proche et finissant avec un signal renvoyé par la portée cible la plus lointaine.

8. Appareil selon la revendication 7, dans lequel les phases des signaux renvoyés sont enregistrées.

9. Appareil selon la revendication 7 ou 8, dans lequel les signaux reçus sont enregistrés et stockés sous une forme numérique.

10. Appareil selon l'une quelconque des revendications précédentes, dans lequel les éléments d'émission (18) émettent un rayonnement électromagnétique ou des ondes acoustiques.

11. Appareil selon la revendication 10, dans lequel le rayonnement électromagnétique est un rayonnement à micro-ondes ou à ondes millimétriques.

12. Appareil selon la revendication 10 ou 11, dans lequel la fréquence du rayonnement électromagnétique de l'onde acoustique peut être ajustée afin de fixer sa longueur d'onde dans le support (28) à une longueur d'onde prédéterminée.

13. Appareil selon la revendication 10, 11 ou 12, dans lequel les caractéristiques de propagation du support sont mesurées par rétrodiffusion ou par émission de signaux d'au moins une fréquence entre au moins deux sondes de capteurs et par mesure du décalage de phase entre les signaux émis et reçus.

14. Appareil selon l'une quelconque des revendications précédentes, dans lequel les éléments d'émission et le dit au moins un élément de réception forme au moins une antenne (10, 12) et l'adaptation d'impédance est effectuée de manière intermédiaire entre l'antenne ou les antennes et le support.

15. Appareil selon la revendication 14, dans lequel l'antenne ou les antennes sont placées face à une feuille correspondant aux caractéristiques du support.

16. Appareil selon la revendication 15, dans lequel la feuille permet de mettre en œuvre un fonctionnement en contact étroit avec une surface rugueuse.

17. Appareil selon la revendication 14, dans lequel l'antenne ou les antennes sont associées avec une feuille d'adaptation d'indice espacée par rapport au support de telle sorte que les réflexions provenant de la feuille et provenant d'une surface du support soient soumises à une interférence destructive.

18. Appareil selon l'une quelconque des revendications précédentes, comprenant en outre un moyen permettant d'atténuer des signaux présentant des longueurs de trajectoires bidirectionnelles plus courtes pour les mettre en correspondance avec ceux provenant de trajectoires plus longues.

19. Appareil selon la revendication 5 ou 6, dans lequel la ou les matrices d'éléments d'antennes sont mobiles afin de se conformer aux profils de surface du support.

20. Appareil selon la revendication 19, dans lequel des capteurs sont prévus pour mesurer le déplacement vertical,
le roulis et le tangage de la matrice ou des matrices de telle sorte que la position de chacun des éléments de la matrice puisse être calculée et que de nouvelles corrections soient apportées à la phase ou à la durée de parcours des signaux reçus pour mettre en œuvre la focalisation après réception.

22. Appareil selon l’une quelconque des revendications 1 à 20, dans lequel les signaux émis sont modulés en fréquence.

23. Appareil selon l’une quelconque des revendications précédentes, dans lequel chacun des signaux reçu est corrélé avec le signal émis.

25. Appareil selon l’une quelconque des revendications 1 à 23, dans lequel, en cours d'utilisation, les éléments de la matrice d'émission sont alimentés un par un, les amplitudes et les phases de la matrice de réception sont enregistrées en parallèle pour tous les éléments de la matrice de réception et tous les retards de parcours concernés, puis pour chaque cellule, le retard de parcours entre chacun des éléments d'émission, via la cellule, et chacun des éléments de réception, est utilisé pour extraire le signal correspondant des données stockées, les signaux sont ensuite mis à l'échelle en puissance et additionnés.

27. Système radar à pénétration dans le sol destiné à la détection des mines, comprenant un appareil conforme à l’une quelconque des revendications 1 à 25.

28. Système d'imagerie médicale comprenant un appareil conforme à l’une quelconque des revendications 1 à 25.

29. Procédé de détection d’un réflecteur de potentiel, comprenant les étapes consistant à :

   actionner des éléments d'émission individuels (18) d’une matrice d'émission bidimensionnelle, un par un, pour émettre des signaux respectifs dans un support soumis à investigation ;
   recevoir des signaux réfléchis par le support soumis à investigation en utilisant au moins un élément de réception et enregistrer les signaux :
   et traiter les signaux enregistrés ou stockés pour amener en coincidence les signaux qui se propagent à partir d'au moins deux des éléments d'émission, via un emplacement de réflecteur de potentiel sélectionné dans le volume, en les décalant, ce qui permet d'effectuer la synthèse de la focalisation des signaux sur l'emplacement de réflecteur de potentiel sélectionné.

30. Procédé de détection d'un réflecteur distant, selon la revendication 29, dans lequel les signaux enregistrés sont décalés afin de synthétiser, dans les signaux reçus, les retards et les décalages de phase qui auraient été introduits entre les éléments d'émission dans la matrice d'émission afin de piloter ou de focaliser l'énergie émise en utilisant des techniques de matrices de phase.
