Description

Field of the Invention

[0001] The present invention refers to a method for generating a cryptographically secure pseudo-random sequence based on a first seed or key.

Background Art

[0002] In many occasions it is necessary to generate a sequence of data which are dependent of a basic key. A first field of application is to generate challenges which are identification numbers generated every ten seconds e.g. and requested in addition to a pin code. This number is only valid during a short time and avoid any replay from a third party. Such generator aims to replace the old strikethrough lists which were printed and sent to the user for the purpose of identification.

[0003] Another field of application is the generation of sub-keys in an encryption algorithm which uses multiple rounds. A first key should be then expanded to produce a lot of sub-keys, each of same being applied to one round. An example of such multiple rounds encryption method is described in the document US 5,214,703.

[0004] We expect two characteristics of such a generation method, i.e. the non predictability of any of the other sequence (or the seed) while knowing one sequence and the reproduction of the sequence in either direction. This last characteristic is specifically used when the sequence is used as encryption sub-key since the decryption needs to use the sub-keys in reverse order.

[0005] A common solution is to apply the seed or the main key to a LFSR (Logical Feedback Shift Register). LFSR generators produce what are called linear recursive sequences (LRS) because all operations are linear. Generally speaking, the length of the sequence, before repetition occurs, depends upon two things, the feedback taps and the initial state. An LFSR of any given size m (number of registers) is capable of producing every possible state during the period \( N = 2^m - 1 \), but will do so only if proper feedback taps, or terms, have been chosen. Such a sequence is called a maximal length sequence, maximal sequence, or less commonly, maximum length sequence.

[0006] Known methods use the output of such shift register to generate the sub-keys block by block to feed the rounds of the encryption process.

[0007] It is generally accepted that knowing one sequence generated that way opens the possibility to access to the other sequences or the seed.

[0008] Another known method can be found in patent US 5745577.

Summary of the Invention

[0009] The aim of this invention is to propose a method to generate sequences or sub-keys based on a main key, in which each sub-key gives no information to recover the main key or any other sub-keys.

[0010] The aim is achieved with a method to generate sub-keys based on a main key (MKEY), comprising the following steps:

- obtaining a first value (A1) by applying on the main key (MKEY) a linear diversification layer by mixing the main key (MKEY) with a constant,

- applying to the first value (A1) a non-linear transformation, this transformation comprising the steps of:
  - obtaining a second value (A2) by applying the first value (A1) to a substitution layer, the substitution layer comprising at least one substitution box (sbox), each substitution box containing at least one table of constants for which the input serves as the pointer and the pointed constant serves as the output,
  - obtaining a third value (A3) by using a diffusion box of multi-permutation type based on the second value (A2),
  - dividing the third value (A3) in N blocks of same size, obtaining the output fourth value (A4) formed by N blocks, each block of the fourth value (A4) being the result of the combination of N-1 blocks of the third value (A3), the missing block being the block of the same index,
  - obtaining the seventh value (A7) by applying on the fourth value (A4) a substitution layer (sigma),
  - obtaining the sub-key (RKEY) by applying to the seventh value (A7) a symmetrical encryption module (SENC),
In case the size of the current key is greater than the main key, the key is truncated and the remaining bits are adjusted to have the same size than the main key.

The aim of the second level is to produce a non-linear diversification of the value A1.

This level comprises five main layers. The first one is a substitution layer.

The purpose of the substitution layer is to transform the input value to an output value without any simple algebraic relationship. The quickest way to achieve the expected confusion result is to use a lookup table containing constants.

Since in this embodiment the input data has a length of 32 bit, the number of constants will be $2^{32}$ values each of 32 bit length.

According to a preferred embodiment, the input data is split in groups of 8-bit length thus reducing the number of constants to 256 bytes.

Then the input data of 32 bit or 64 bit is divided in bytes of 8 bit and applied to the substitution box to obtain an output of 8 bit. The input data is used as address pointer and the pointed constant is the output.

Depending on the implementation method, the constant tables are the same for all groups of the input data (32 bit or 64 bit). In another embodiment, the constant tables are different for each group of the input data.

The constants stored in this table are a fixed permutation of numbers which are all different, encoded by a number of bits equal to the table width.

The second main layer of this non-linear level is the multi-permutation matrix. The multi-permutation matrix is a square matrix with property that every possible square sub-matrix has a determinant different of zero; the elements of the matrix are elements of a finite field. The mixing operation consists in multiplying a vector of input elements by the matrix, resulting in a vector which is defined to be the output.

The third layer is a mixing layer. The input value is divided into several blocks having the same size. For a given input block i, the output block i is the result of the XOR function of all input blocks except the block i.

The fourth layer is another substitution layer which apply the same operation to the input value as the first layer.

The purpose of the substitution layer is to transform the input value to an output value without any simple algebraic relationship. The quickest way to achieve the expected confusion result is to use a lookup table containing constants.

In a particular embodiment of the invention, it is interesting to reuse the previous layers also for the encryption round. This is why instead of reusing a known encryption round, the following steps will be executed as encryption round on the input value A5 to obtain the output value RA:

- dividing the input value A5 into at least two values Y0L and Y0R,
- mixing the at least two values Y0L and Y0R to form a mixed value Y1,
- obtaining a value Y2 by mixing a first part A1H of the value A1 with the value Y1,
- obtaining a value Y3 by applying the value Y2 to a substitution layer, the substitution layer comprising at least one substitution box (sbox), each substitution box containing at least one table of constants for which the input serves as the pointer and the pointed constant serves as the output,
- obtaining a value Y4 by using a diffusion box of multi-permutation type based on the value Y3,
- obtaining a value Y5 by mixing a second part A1L of the value A1 with the value Y4,
- obtaining a value Y6 by applying to the value Y5 a substitution layer,
- obtaining a value Y7 by mixing a first part RAH of the sub-key RA with the value Y6,
- mixing the value Y7 with the initial at least two values Y0L and Y0R to obtain at least two values Y8L and Y8R, Y8L and Y8R representing the output value RA of this encryption round.

According to another embodiment, an additional transformation is added on the value A4 before applying this value to the substitution layer.

This transformation is a mere addition with a constant, executed with an XOR function.

In case the provided key length is different that the size of the main key R, the current key should be firstly adjusted to have the same size than the main key.

In case the size of the current key is greater than the main key, the key is truncated and the remaining bits are
added to the truncated part (XOR function).

[0032] In case the current key size is smaller than the main key, a padding will be added. In order to avoid that this padding will reduce the quality of the diversification, this padding is shuffled with the current key so that the padding bits are spread all along the resulting key.

[0033] The above characteristics allows to generate sub-keys having the following advantages:

- cryptographically safe
- generated in bi-directional, forward and backward mode
- using main key of variable length, preferably of 8 bits block.

Brief description of the drawings

[0034]

- The figure 1 shows the block diagram of the generation of sub-keys based on the main key,
- The figure 2 shows the non-linear module based on a 128 bits input key and 64 bits output,
- The figure 3 shows the non-linear module based on a 256 bits input key and 64 bits output,
- The figure 4 shows the block diagram of the main module in the encryption process,
- The figure 5 shows the encryption process using two MOD modules and an orthomorphism function OR,
- The figure 6 shows the block diagram of the orthomorphism function,
- The figure 7 shows the internal part of the main encryption module MOD.

Detailed description of the invention

[0035] The figure 1 describes the main structure of this key generation. The first stage is the key length adjustment LA. The input key AKEY in this example has a smaller size than the expected size. The process PPr adds padding data in the input key AKEY so that the size will be the nominal size. This padding data is simply added at the end of the key. The resulting key PKEY has the nominal size, e.g. 128 or 256 bits.

[0036] The second process is the padding shuffling process MPr. It is important to mix the padding data within the key so that the padding data are not always at the same position. This mixing is made through a Fibonacci recursion, which takes as input a key PKEY with length ek (expressed in bits). More formally, the padded key PKEY is seen as an array of ek/8 bytes PKEY(8), 0 ≤ l ≤ ek/8 -1, and is mixed according to:

\[
MKEY(8) = PKEY(8) \oplus (MKEY(8-1) + MKEY(8-2) \mod 2^8) \quad 0 \leq i \leq \frac{ek}{8} - 1
\]

[0037] The next stage is the diversification stage LD which is the linear diversification part DPr. In case that the input key has already the expected size, this key will be directly loaded in the MKEY register.

[0038] The aim of this diversification part DPr is to produce a linear diversification of the key MKEY by mixing the key MKEY with an initializing vector. For each sub-key generated, the initializing vector is different. Different embodiments could be used to produce this initializing vector.

[0039] The simplest way is to store an array of constants, each constant having the same size than the key size and acting as initializing vector. The number of initializing vectors is dependent of the number of rounds used for the encryption process or the number of sub-keys used by the system.

[0040] In a second embodiment, the initializing vectors are generated through a diversification part DPr which is based on a pseudo-random stream using a Linear Feedback Shift Register LFSR. An initial constant is loaded into the LFSR (24 bits in this example) and the output of this register, i.e. the initializing vector, is mixed with the key MKEY to produce the key KKEY.

[0041] This embodiment has the advantage to minimize the quantity of the data stored since the initializing vectors
are not stored but are generated with the LFSR, only the initial constant is stored or is part of the algorithm.

[0042] In a third embodiment, the key itself is loaded in a LFSR and the LFSR output is directly the input of the next module i.e. the key DKEY.

[0043] The next stage, so called non-linear diversification stage NLD, is the non linear module NLxPR. This stage is described in details in the figures 2 and 3.

[0044] In the figure 2 the key DKEY (which corresponds with the value A1) is divided into four parts and applied to a substitution layer sigma, comprising at least one substitution box (sbox), each substitution box containing a table of constants for which the input serves as the pointer and the pointed constant serves as the output. The output data A2 is the output of the sigma box. One method to generate this constant table is to use a pseudorandom generator. When generating the table, one should remove all duplicate values so that each constant in this table is unique.

[0045] Depending on the implementation, the number of substitution box (sbox) can vary since each box in the present embodiment has 8-bit data input. The input data applied to the sigma module is split into parts of 8-bit length and applied to the substitution box. The output of each box is then concatenated to form the output of the module sigma.

[0046] The next stage is a matrix of multi-permutation type mu. This matrix in a diffusion box of (n,n) multi-permutation type. The input of one mu block is divided into n input vectors. For this example, we will choose a matrix of 4 elements. The diffusion box consists in multiplying the four input vectors (Aa, Ab, Ac, Ad) by a square matrix 4x4 Mu4, whose elements belong to the finite field with 256 elements; these elements are denoted Mu(i, j), where i refers to the row index and j to the column index. The result of the multiplication of the input vector (Aa, Ab, Ac, Ad) by the matrix Mu4 is a vector (Ya, Yb, Yc, Yd) where these values are obtained as follows:

\[
Ya = \text{Mu4(1, 1)}Aa + \text{Mu4(1, 2)}Ab + \text{Mu4(1, 3)}Ac + \text{Mu4(1, 4)}Ad
\]

\[
Yb = \text{Mu4(2, 1)}Aa + \text{Mu4(2, 2)}Ab + \text{Mu4(2, 3)}Ac + \text{Mu4(2, 4)}Ad
\]

\[
Yc = \text{Mu4(3, 1)}Aa + \text{Mu4(3, 2)}Ab + \text{Mu4(3, 3)}Ac + \text{Mu4(3, 4)}Ad
\]

\[
Yd = \text{Mu4(4, 1)}Aa + \text{Mu4(4, 2)}Ab + \text{Mu4(4, 3)}Ac + \text{Mu4(4, 4)}Ad
\]

[0047] Here "+" denotes the addition in the finite field and "*" its multiplication. The elements of Mu4 are chosen such that the amount of computations needed to evaluate the four above expressions is minimal. The number of multiplications by the constant "1" (thereafter denoted "identities") has therefore been chosen to be as large as possible.

[0048] The output value A3 of the mu block is the concatenation of the four output values Ya, Yb, Yc, Yd.

[0049] The next stage is a mixing step. It consists in dividing the value A3 in N blocks of same size, and obtaining the output value A4 formed by N blocks, each block of the value A4 being the result of the combination of N-1 blocks of the value A3, the missing block being the block of the same index.

[0050] In the example of the figure 2, the number of blocks is 4. The three remaining blocks are mixed together to form part of the value A4.

[0051] The next stage is an adder stage which add a constant so that an unpredictable element is inserted in the process.

[0052] The resulting value A5 of the is applied to a conditional inverter, i.e. the inversion is enabled when padding data was added in the input key AKEY. When enabled, all bits of the value A5 are inverted to obtain the value A6. The inversion is made in case that padded data was added to the input key AKEY. The aim of this stage is to have a different behavior in case that a full size key is used and a padding key. A full size key can have theoretically the same value when a smaller key is inputted and padding data is added. When padding information is added to complete the input key to have the expected size, the inversion of the data A5 is made so that to introduce an additional diversification in the course of the generation process.

[0053] The resulting value A6 is then applied to a substitution layer sigma which is already described above.

[0054] The output value of the substitution layer A7 is reduced in size by half by mixing two elements

[0055] This reduced value A8 is then applied to a symmetrical encryption module SENC in which the key is taken
from the main input of the process (i.e. DKEY). As already stated, this module is basically a simple symmetrical encryption process. In the frame of this invention, instead of using a well known encryption process such as IDEA, DES ... the encryption process is carried out using the process described in the patent application EP 1480371 of the same Applicant. The minimum number of rounds is determined so that the entire key DKEY is used. Since the key is longer than the input size of the encryption step, the key is divided and applied to different rounds serially connected.

[0056] This encryption process is described in reference with the figures 4 to 7.

[0057] The Figure 4 shows the skeleton of the encryption process which represents the module MOD. The entry data of 64 bit in the present example, represented in two parts X0L and X0R of 32 bit each, are firstly mixed within the mixing element MX to obtain the X1 value. This mixing element aims to provide a 32 bit image of two times 32 bit of data. This could be achieved in different ways such as using XOR function, addition with modulo, or by using any group law.

[0058] The next step is illustrated with the block f32 which has a 32 bit input X1 and a 32 bits output X7 as well as using a sub-key DK. The detailed description of this block is given with reference to figure 7 (see below).

[0059] The output X7 of the block f32 is applied to the two mixing blocks MX which are connected with the two entries X0L and X0H.

[0060] The resulting data X8L and X8R represent the two 64 bits output X8 of the module MOD.

[0061] The figure 5 shows the whole encryption process using two identical modules MOD, i.e. MOD1 and MOD2. The input data A8 is formed by two parts X0L1 and X0R1, each of 32-bit length.

[0062] The symmetrical encryption process is referenced SENC in the figure 2. This module corresponds with the block diagram of the figure 5.

[0063] The outputs X0L1 and X0R1 are then used as entries in the first module MOD1. This first module processes the data while using a first sub-key DK1. DK1 is a part of the main key DKEY. The processing for X0L1 and X0R1 is the same as described according to Fig. 4. The outputs of this first module MOD1 are two outputs X8L1 and X8R1. An orthomorphism function is applied to one of these outputs, for example X8L1 as illustrated on Fig. 5. The output resulting from this orthomorphism function is referenced as X0L2. The other value X8R1 resulting from the processing by the first module MOD1 is used as input, as well as the output X0L2 resulting from the orthomorphism function, in a second processing module MOD2. The module MOR is the result of a module MOD with an orthomorphism function OR in one of the output of this module.

[0064] This second module MOD2 will process their input data based on a second part DK2 of the main key DKEY. The outputs of this second module are referenced as X8L2 and X8R2 on Fig. 4. These outputs are assembled to form the sub-key RKEY within the assembler module AS.

[0065] The function of this assembler module AS could be achieved in different ways such as selecting the lowest bits for X8L2 and the highest bits for X8R2, or every odd bit for X8L2 and even bit for X8R2. Other methods of assembling the resulting data RKEY could be used as long as all the bits of RKEY are comprised in X8L2 and X8R2.

[0066] The figure 7 shows in detail, the functions of the block f32 of the Figure 4. In this block, a 32-bits length data X1 is the input. This data are separated in blocks of 8-bit length (X1a, X1b, X1c, X1d) through a splitting block SPMU, also mentioned X1’ in the figure 7.

[0067] This block has the function to split the input data X1 so that all bits of the resulting value X1a, X1b, X1c and X1d are present in X1. These four values are mixed with the highest value DKH of the key DK, which could be DK1 or DK2 depending on the module concerned (MOR or MOD) to form the four values X2a, X2b, X2c and X2d.

[0068] The generation of the two sub-keys DKL and DKH is made through the splitting module SP.

[0069] Each of these values X2a to X2d are applied to a substitution layer, comprising at least one substitution box (sbox), each substitution box containing a table of constants for which the input serves as the pointer and the pointed constant serves as the output. The output data is referenced as X3a, X3b, X3c, X3d (forming the value X3) on Fig. 7.

[0070] This substitution layer was already described in reference with the figure 2 while describing the module sigma. The resulting value is X3.

[0071] The same apply for the Mu4 module which correspond to the mu module of the figure 2. The resulting value is X4.

[0072] The output data X4 of data is then mixed with a second part DKL of the sub-key DK to obtain a value X5a, X5b, X5c, X5d (forming the value X5).

[0073] Each of these values X5a to X5d is then applied to a substitution block (sbox) to obtain a value X6a, X6b, X6c, X6d (forming the value X6). These values are mixed with a first part DKH of the sub-key DK to obtain new values X7a, X7b, X7c, X7d (forming the value X7).

[0074] Then these values X7a, X7b, X7c, X7d are assembled to form the output data X7 within the assembler module AS as described in respect with the figure 5. This data corresponds to the output data X7 of block f32 in Fig. 4

[0075] The figure 6 is an illustration of an embodiment of the orthomorphism function. The input data is noted ZI and the output data is noted ZO. The data length is not an issue for this function. The input data Z1 is first divided into two values ZL andZR of the same size with the splitting module SP. Then the two values are mixed with the so called MX mixing element and the output of the element is applied to the assembler unit AS. The other split value ZR is directly applied to the assembler module AS without modification. This module comprises two inputs and combines these data.

EP 1 661 296 B1
to form the output value ZO. This module works inversely than the splitting module SP. The particularity of this embodiment is that the inputs of the assembler module are crossed relative to the outputs of the splitting module SP. The right output ZR of the splitting module SP is applied to the left input of the assembler module AS and the left output ZL of the splitting module SP, after being mixed with the other output of the splitting module SP, is applied to the right input of the assembler module AS.

[0076] The figure 3 is another embodiment to produce a sub-key RKEY based on a main key DKEY. While facing with modules which can only process a data of limited size, in case that longer keys are processed, it is necessary to divide the input key DKEY in more elements and handle them in parallel. The principle described with respect of the figure 2 remains the same with one exception while forming the value A4.

[0077] For simplification purposes, the number of elements mixed together from the value X3 is limited to three.

[0078] At the stage of the symmetrical encryption process SENC, the input key DKEY is divided in four parts and applied to three independent encryption modules MOR64, these modules having an orthomorphism function applied to the half of the resulting value The last module MOD64 is a one round encryption process without the orthomorphism function.

[0079] From the value A8 to RKEY, the encryption process is carried out in four rounds, each round using one part of the input key DKEY. The first three rounds are using a module MOR i.e. having an orthomorphism function in one of the output of the MOD module and the last round is of the type MOD, i.e. without orthomorphism function.

[0080] One important point is to generate the sub-keys in the reverse order. This particularity is useful when the sub-keys are used in an multiple rounds encryption process.

[0081] This is achieved at the stage of the linear diversification part DPr. The set of initializing vectors used to mix with the key MKEY is applied in the reverse order. When the initializing vectors are produced with a LFSR, the register is clocked in the reverse order (backward process) and the initial value loaded in the register is the end value representing the last initializing vector used during the forward process.

Claims

1. Method to generate a sub-key based on a main key (MKEY), comprising the following steps:

   - obtaining a first value (A1) by applying to the main key (MKEY) a linear diversification layer by mixing the main key (MKEY) with a constant,
   - applying to the first value (A1) a non-linear transformation, this transformation comprising the steps of:
     - obtaining a second value (A2) by applying the first value (A1) to a substitution layer, the substitution layer comprising at least one substitution box (sbox), each substitution box containing at least one table of constants for which the input serves as the pointer and the pointed constant serves as the output,
     - obtaining a third value (A3) by using a diffusion box of multi-permutation type based on the second value (A2),
     - dividing the third value (A3) in N blocks of same size, obtaining an output fourth value (A4) formed by N blocks, each block of the fourth value (A4) being the result of the combination of N-1 blocks of the third value (A3), the missing block being the block of the same index,
     - obtaining a seventh value (A7) by applying to the fourth value (A4) a substitution layer (sigma),
     - obtaining the sub-key (RKEY) by applying to the seventh value (A7) a symmetrical encryption module (SENC), the first value (A1) serving as the key input for this module.

2. The method of claim 1, characterized in that a provided key (AKEY) is of smaller size than the main key (MKEY), this method consisting in obtaining the main key (MKEY) from the provided key (AKEY) according to the followings steps:

   - adding padding data in order to complete the provided key (AKEY) up to the size of the main key (MKEY),
   - mixing the padding data with the provided key (AKEY) so that the padding bits are spread all along the resulting key (DKEY).

3. The method of claims 1 or 2, characterized in that the constant mixed with the main key (MKEY) to obtain the first value (A1) is pseudo-randomly generated using a LFSR loaded with a first constant.

4. The method of claims 1 to 3, characterized in that in case that the input size of the symmetrical encryption module (SENC) is smaller than the size of the seventh value (A7), the method comprises the step of dividing the seventh
value (A7) by a multiple of two and mixing two by two the resulting portion up to input size of the symmetrical encryption module (SENC).

5. The method of claims 1 to 4, characterized in that a constant is added on the fourth value (A4) before applying to the substitution layer (sigma).

6. The method of claims 2 to 5, characterized in that an inversion is made on all bits of input value (A6) of the substitution layer (sigma) while padding data is added on the provided key (AKEY).

**Patentansprüche**

1. Verfahren zur Erzeugung eines auf einem Hauptschlüssel (MKEY) beruhenden Unterschlüssels mit den folgenden Schritten:

- Gewinnung eines ersten Wertes (A1) durch Anwendung einer linearen Diversifikationsschicht auf den Hauptschlüssel (MKEY), indem der Hauptschlüssel (MKEY) mit einer Konstanten vermischt wird;
- Anwendung einer nichtlinearen Transformation auf den ersten Wert (A1), wobei die nichtlineare Transformation die Schritte umfasst:
  - Gewinnung eines zweiten Wertes (A2) durch Anwendung des ersten Wertes (A1) auf eine Substitutionschicht, wobei die Substitutionsschicht zumindest eine Substitutionsbox (sbox) umfasst und jede Substitutionsbox zumindest eine Konstantentabelle enthält, bei der die Eingabe als Zeiger und die gezeigte Konstante als die Ausgabe dient,
  - Gewinnung eines auf dem zweiten Wert (A2) beruhenden dritten Wertes (A3) durch Verwendung einer Diffusionsbox des Multipermutations-Typs,
  - Aufteilung des dritten Wertes (A3) in N Blöcke gleicher Grösse, Gewinnung eines aus N Blöcken gebildeten vierten Ausgabewertes (A4), wobei jeder Block des vierten Wertes (A4) das Ergebnis der Kombination von N - 1 Blöcken des dritten Wertes (A3) ist und der fehlende Block der Block mit dem gleichen Index ist,
  - Gewinnung eines siebenten Wertes (A7) durch Anwendung einer Substitutionsschicht (sigma) auf den vierten Wert (A4),
  - Gewinnung des Unterschlüssels (RKEY) durch Anwendung eines symmetrischen Verschlüsselungsmoduls (SENC) auf den siebenten Wert (A7), wobei der erste Wert (A1) als eingegebener Schlüssel für diesen Modul dient.

2. Verfahren nach Anspruch 1, dadurch gekennzeichnet, dass ein gelieferter Schlüssel (AKEY) eine geringere Grösse als der Hauptschlüssel (MKEY) hat, wobei dieses Verfahren darin besteht, den Hauptschlüssel (MKEY) aus dem gelieferten Schlüssel (AKEY) über die folgenden Schritte zu gewinnen:

- Hinzufügung von Paddingdaten, um den gelieferten Schlüssel (AKEY) auf die Grösse des Hauptschlüssels (MKEY) aufzufüllen,
- Vermischung der Paddingdaten mit dem gelieferten Schlüssel (AKEY), so dass die Padding-Bits über die gesamte Länge des anfallenden Schlüssels (DKEY) verteilt werden.

3. Verfahren nach Ansprüchen 1 oder 2, dadurch gekennzeichnet, dass die Konstante, die mit dem Hauptschlüssel (MKEY) vermischt wird, um den ersten Wert zu gewinnen, unter Verwendung eines mit einer ersten Konstanten geladenen LFSR pseudozufallsgeneriert wird.

4. Verfahren nach Ansprüchen 1 bis 3, dadurch gekennzeichnet, dass in Fällen, in denen die Eingabegrösse des symmetrischen Verschlüsselungsmoduls (SENC) kleiner als der siebente Wert (A7) ist, das Verfahren den Schritt umfasst, den siebenten Wert (A7) durch ein Mehrfaches von zwei zu teilen und den anfallenden Anteil paarweise bis zur Grösse der Eingabe des symmetrischen Verschlüsselungsmoduls (SENC) zu vermindern.

5. Verfahren nach Ansprüchen 1 bis 4, dadurch gekennzeichnet, dass eine Konstante vor der Anwendung auf die Substitutionsschicht (sigma) zum vierten Wert (A4) hinzugefügt wird.

6. Verfahren nach Ansprüchen 2 bis 5, dadurch gekennzeichnet, dass eine Inversion an allen Bits des Ausgabewertes (A6) der Substitutionsschicht (sigma) ausgeführt wird, während Paddingdaten zum gelieferten Schlüssel (AKEY)
Revendications

1. Méthode de génération d’une clé secondaire basée sur une clé principale (MKEY), comprenant les étapes suivantes:
   - obtenir une première valeur (A1) en appliquant une couche de diversification linéaire à la clé principale (MKEY) en mélangeant la clé principale (MKEY) avec une constante,
   - appliquer une transformation non linéaire à la première valeur (A1), cette transformation comprenant les étapes suivantes:
     - obtenir une seconde valeur (A2) en appliquant la première valeur (A1) à une couche de substitution, la couche de substitution comprenant au moins une boîte de substitution (sbox), chaque boîte de substitution contenant au moins une table de constantes pour laquelle l’entrée sert de pointeur et la constante pointée sert de sortie,
     - obtenir une troisième valeur (A3) basée sur la seconde valeur (A2) en utilisant une boîte de diffusion de type à-permutation multiple,
     - diviser la troisième valeur (A3) en N blocs de même taille, obtenir une quatrième valeur de sortie (A4) formée de N blocs, chaque bloc de la quatrième valeur (A4) étant le résultat de la combinaison de N-1 blocs de la troisième valeur (A3), le bloc manquant étant le bloc du même index,
     - obtenir une septième valeur (A7) en appliquant une couche de substitution (signal) à la quatrième valeur (A4)
   - obtenir la clé secondaire (RKEY) en appliquant un module d’encryption symétrique à la septième valeur (A7), la première valeur (A1) servant d’entrée de clé pour ce module.

2. Méthode selon la revendication 1, caractérisée en ce qu’une clé fournie (AKEY) est de taille inférieure à la clé principale (MKEY), cette méthode consistant à obtenir la clé principale (MKEY) à partir de la clé fournie (AKEY) selon les étapes suivantes:
   - ajouter des données de remplissage de manière à compléter la clé fournie (AKEY) jusqu’à la taille de la clé principale (MKEY),
   - mélanger les données de remplissage avec la clé fournie (AKEY) de façon à répartir les bits de remplissage tout au long de la clé résultante (DKEY).

3. Méthode selon les revendications 1 ou 2 caractérisée en ce que la constante mélangée avec la clé principale (MKEY) pour obtenir la première valeur (A1) est générée de manière pseudo-aléatoire en utilisant un LFSR chargé avec une première constante.

4. Méthode selon les revendications 1 à 3 caractérisée en ce que dans le cas où la taille d’entrée du module d’encryption symétrique (SENC) est inférieure à la taille de la septième valeur (A7), la méthode comprend l’étape de division de la septième valeur (A7) par un multiple de deux et de mélange deux par deux de la partie résultante jusqu’à la taille d’entrée du module d’encryption symétrique (SENC).

5. Méthode selon les revendications 1 à 4 caractérisée en ce qu’une constante est ajoutée à la quatrième valeur (A4) avant l’application à la couche de substitution (sigma).

6. Méthode selon les revendications 2 à 5 caractérisée en ce qu’une inversion est effectuée sur tous les bits de la valeur d’entrée (A6) de la couche de substitution (sigma) pendant que des données de remplissage sont ajoutées à la clé fournie (AKEY).
