Techniques to determine the rate for a data transmission in an OFDM system. The maximum data rate that may be reliably transmitted over a given multipath (non-flat) channel by the OFDM system is determined based on a metric for an equivalent (flat) channel. For the given multipath channel and a particular rate (which may be indicative of a particular data rate, modulation scheme, and coding rate), the metric is initially derived from an equivalent data rate and the particular modulation scheme. A threshold SNR needed to reliably transmit the particular data rate using the particular modulation scheme and coding rate is then determined. The particular rate is deemed as being supported by the multipath channel if the metric is greater than or equal to the threshold SNR. Incremental transmission is used to account for errors in the determined data rate.
BACKGROUND

Field

[0001] The present invention relates generally to data communication, and more specifically to techniques for selecting rate for a wireless (e.g., OFDM) communication system.

Background

[0002] Wireless communication systems are widely deployed to provide various types of communication such as voice, data, and so on. These systems may implement orthogonal frequency division multiplex (OFDM) modulation, which may be capable of providing high performance for some channel environments. In an OFDM system, the system bandwidth is effectively partitioned into a number of (N_F) frequency subchannels (which may be referred to as sub-bands or frequency bins). Each frequency subchannel is associated with a respective subcarrier (or frequency tone) upon which data may be modulated. Typically, the data to be transmitted (i.e., the information bits) is encoded with a particular coding scheme to generate coded bits, and the coded bits may further be grouped into multi-bit symbols that are then mapped to modulation symbols based on a particular modulation scheme (e.g., M-PSK or M-QAM). At each time interval that may be dependent on the bandwidth of each frequency subchannel, a modulation symbol may be transmitted on each of the N_F frequency subchannels.

[0003] The frequency subchannels of an OFDM system may experience different channel conditions (e.g., different fading and multipath effects) and may achieve different signal-to-noise-and-interference ratios (SNRs). Each transmitted modulation symbol is affected by the frequency response of the communication channel at the particular frequency subchannel via which the symbol was transmitted. Depending on the multipath profile of the communication channel, the frequency response may vary widely throughout the system bandwidth. Thus, the modulation symbols that collectively form a particular data packet may be individually received with a wide range of SNRs via the N_F frequency subchannels, and the SNR would then vary correspondingly across the entire packet.

[0004] For a multipath channel having a frequency response that is not flat or constant, the number of information bits per modulation symbol (i.e., the data rate or information rate) that may be reliably transmitted on each frequency subchannel may be different from subchannel to subchannel. Moreover, the channel conditions typically vary over time. As a result, the supported data rates for the frequency subchannels also vary over time.

[0005] Since the channel conditions experienced by a given receiver are typically not known a priori, it is impractical to transmit data at the same transmit power and/or data rate to all receivers. Fixing these transmission parameters would likely result in a waste of transmit power, the use of sub-optimal data rates for some receivers, and unreliable communication for some other receivers, all of which leads to an undesirable decrease in system capacity. The different transmission capabilities of the communication channels for different receivers plus the time-variant and multipath nature of these channels make it challenging to effectively code and modulate data for transmission in an OFDM system.

[0006] There is therefore a need in the art for techniques to select the proper rate for data transmission in a wireless (e.g., OFDM) communication system having the channel characteristics described above.

SUMMARY

[0007] Aspects of the invention provide techniques to determine and select the rate for a data transmission in a wireless (e.g., OFDM) communication system. These techniques may be used to provide improved system performance for an OFDM system operating with a multipath (non-flat) channel or a flat channel.

[0008] In an aspect, the maximum data rate that may be reliably transmitted over a given multipath channel by the OFDM system is determined based on a metric for an equivalent frequency flat channel (e.g., a channel having a flat frequency response). For the given multipath channel, which is defined by a particular frequency response and a particular noise variance, the OFDM system may be capable of achieving a particular equivalent data rate D_{equiv} using a particular modulation scheme M(r). The equivalent data rate, D_{equiv}, may be estimated based on a particular channel capacity function (e.g., a constrained channel capacity function or some other function). The metric, which is an estimate of the SNR required by the equivalent frequency flat channel to reliably transmit at the equivalent data rate D_{equiv} using the modulation scheme M(r), is then determined for D_{equiv} using M(r) and further based on a particular function g(D_{equiv}, M(r)). A threshold SNR needed for the equivalent channel to reliably transmit a particular data rate D(r) using the modulation scheme M(r) and coding rate C(r) is then determined. The data rate D(r) is then deemed as being supported by the multipath channel if the metric is greater than or equal to the threshold SNR.

[0009] In another aspect, an incremental transmission (IT) scheme is provided and may be advantageously used in
conjunction with the rate selection of the first aspect to reduce the amount of back-off and to improve system throughput. The IT scheme transmits a given packet of data using one or more discrete transmissions, one transmission at a time and up to a particular limit. The first transmission for the packet includes sufficient amount of data such that the packet can be recovered error-free at the receiver based on the expected channel conditions. However, if the first transmission is excessively degraded by the communication channel such that error-free recovery of the packet is not achieved, then an incremental transmission of an additional amount of data for the packet is performed. The receiver then attempts to recover the packet based on the additional data in the incremental transmission and all data previously received for the packet. The incremental transmission by the transmitter and the decoding by the receiver may be attempted for one or more times, until the packet is recovered error-free or the maximum number of incremental transmissions is reached.

Various aspects and embodiments of the invention are described in further detail below. The invention further provides methods, receiver units, transmitter units, receiver systems, transmitter systems, systems, and other apparatuses and elements that implement various aspects, embodiments, and features of the invention, as described in further detail below.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1A is a diagram of a simplified model of an OFDM communication system; FIG. 1B is a diagram that graphically illustrates rate selection for a multipath channel using an equivalent channel; FIG. 2 is a flow diagram of an embodiment of a process for selecting data rate for use in the OFDM system based on a metric \( \Psi \); FIG. 3 is a block diagram of an embodiment of a transmitter system and a receiver system, which are capable of implementing various aspects and embodiments of the invention; FIG. 4 is a block diagram of an embodiment of a transmitter unit; and FIG. 5 is a block diagram of an embodiment of a receiver unit.

DETAILED DESCRIPTION

The techniques described herein for determining and selecting the rate for a data transmission may be used for various wireless communication systems comprising one or more independent transmission channels, e.g., multiple-input multiple-output (MIMO) systems. For clarity, various aspects and embodiments of the invention are described specifically for an orthogonal frequency division multiplex (OFDM) system, where the independent transmission channels are the frequency subchannels or bins formed by dividing the total system bandwidth.

The modulation may be achieved by grouping sets of coded bits to form multi-bit symbols and mapping each multi-bit symbol to a point in a signal constellation corresponding to the particular modulation scheme (e.g., QPSK, M-PSK, or M-QAM) selected for each frequency subchannel used to transmit the symbol. Each mapped signal point corresponds to a modulation symbol.

In an embodiment, the data rate is determined by a data rate control, the coding scheme(s) are determined by a coding control, and the modulation scheme(s) are determined by a modulation control, all of which are provided by a controller 130 based on feedback information received from a receiver 150.

A pilot may also be transmitted to the receiver to assist it perform a number of functions such as channel estimation, acquisition, frequency and timing synchronization, coherent data demodulation, and so on. In this case, pilot data is provided to encoder/modulator 114, which then multiplexes and processes the pilot data with the traffic data.

For OFDM, the modulated data (i.e., the modulation symbols) is then transformed to the time domain by an inverse fast Fourier transformer (IFFT) 116 to provide OFDM symbols, with each OFDM symbol corresponding to a time representation of a vector of \( N_f \) modulation symbols to be transmitted on \( N_f \) frequency subchannels in a transmission symbol period. In contrast to a single carrier "time-coded" system, the OFDM system effectively transmits the modulation symbols "in the frequency domain", by sending in the time domain the IFFT of the modulation symbols that represent the traffic data. The OFDM symbols are further processed (not shown in FIG. 1A for simplicity) to generate a modulated signal, which is then transmitted over a wireless communication channel to the receiver. As shown in FIG. 1A, the communication channel has a frequency response of \( H(f) \) and further degrades the modulated signal with additive white Gaussian noise (AWGN) of \( n(t) \).
At receiver 150, the transmitted modulated signal is received, conditioned, and digitized to provide data samples. A fast Fourier transformer (FFT) 160 then receives and transforms the data samples to the frequency domain, and the recovered OFDM symbols are provided to a demodulator/decoder 162 and a channel estimator 164. Demodulator/decoder 162 processes (e.g., demodulates and decodes) the recovered OFDM symbols to provide decoded data, and may further provide a status of each received packet. Channel estimator 164 processes the recovered OFDM symbols to provide estimates of one or more characteristics of the communication channel, such as the channel frequency response, the channel noise variance, the signal-to-noise-and-interference ratio (SNR) of the received symbols, and so on.

A rate selector 166 receives the estimates from channel estimator 164 and determines a suitable "rate" that may be used for all or a subset of the frequency subchannels available for use for data transmission. The rate is indicative of a set of specific values for a set of parameters. For example, the rate may indicate (or may be associated with) a specific data rate to be used for the data transmission, a specific coding scheme and/or coding rate, a specific modulation scheme, and so on.

A controller 170 receives the rate from rate selector 166 and the packet status from demodulator/decoder 162 and provides the appropriate feedback information to be sent back to transmitter 110. This feedback information may include the rate, the channel estimates provided by channel estimator 164, an acknowledgment (ACK) or negative acknowledgment (NACK) for each received packet, some other information, or any combination thereof. The feedback information is used to increase the efficiency of the system by adjusting the data processing at the transmitter such that the data transmission is performed at the best known settings of power and rate that may be supported by the communication channel. The feedback information is then sent back to transmitter 110 and used to adjust the processing (e.g., the data rate, coding, and modulation) of the data transmission to receiver 150.

In the embodiment shown in FIG. 1A, the rate selection is performed by receiver 150 and the selected rate is provided to transmitter 110. In other embodiments, the rate selection may be performed by the transmitter based on feedback information provided by the receiver, or may be performed jointly by both the transmitter and receiver.

A major challenge for an OFDM system is then to determine the maximum data rate that may be used for data transmission while achieving a particular level of performance, which may be quantified by a particular packet error rate (PER), frame error rate (FER), bit error rate (BER), or some other criterion. For example, the desired level of performance may be achieved by maintaining the PER within a small window around a particular nominal value (e.g., $P_e = 1\%$). In a typical communication system, a set of specific and discrete data rates may be defined, and only these data rates may be available for use. Each data rate, $D(r)$, may be associated with a specific modulation scheme or constellation, $M(r)$, and a specific coding rate, $C(r)$. Each data rate would further require a particular SNR(r), which is the minimum SNR at which the resulting PER for the data transmission at that data rate is less than or equal to the desired PER, $P_e$. This SNR(r) assumes that the communication channel is AWGN (i.e., with a flat frequency response

\[ \hat{Y}(k) = Y(k)H(k) + N(k) \],

Eq (1)

where $k$ is an index for the frequency subchannels of the OFDM system, i.e., $k = 0, 1, \ldots, N_F - 1$, where $N_F$ is the number of frequency subchannels;

$Y(k)$ are the modulation symbols transmitted on the $k$-th frequency subchannel, which are derived based on a particular modulation scheme used for the $k$-th frequency subchannel;

$H(k)$ is the frequency response of the communication channel, represented in "quantized" form for each frequency subchannel;

$N(k)$ represents the FFT of a sequence of $N_F$ samples of the time-domain noise, i.e., $\text{FFT} \{ n(kT) \}$ for $k = 0, 1, \ldots, N_F - 1$; and

$T$ is the sampling period.

In a single carrier system, the transmitted symbols may all be received at the receiver at approximately the same SNR. The relationship between the SNR of a "constant SNR" packet and the probability of error for the packet is well known in the art. As an approximation, the maximum data rate supported by the single carrier system with a particular achieved SNR may be estimated as the maximum data rate supported by an AWGN channel with the same SNR. The main characteristic of the AWGN channel is that its frequency response is flat or constant across the entire system bandwidth.

However, in an OFDM system, the modulation symbols that make up a packet are transmitted across multiple frequency subchannels. Depending on the frequency response of the frequency subchannels used to transmit the packet, the SNR may vary across the entire packet. This problem of "varying SNR" packet is exacerbated as the system bandwidth increases and for a multipath environment.

A major challenge for an OFDM system is then to determine the maximum data rate that may be used for data transmission while achieving a particular level of performance, which may be quantified by a particular packet error rate (PER), frame error rate (FER), bit error rate (BER), or some other criterion. For example, the desired level of performance may be achieved by maintaining the PER within a small window around a particular nominal value (e.g., $P_e = 1\%$). In a typical communication system, a set of specific and discrete data rates may be defined, and only these data rates may be available for use. Each data rate, $D(r)$, may be associated with a specific modulation scheme or constellation, $M(r)$, and a specific coding rate, $C(r)$. Each data rate would further require a particular SNR(r), which is the minimum SNR at which the resulting PER for the data transmission at that data rate is less than or equal to the desired PER, $P_e$. This SNR(r) assumes that the communication channel is AWGN (i.e., with a flat frequency response
across the entire system bandwidth, or \( H(k) = H \) for all \( k \)). Typically, the communication channel between the transmitter and receiver is not AWGN, but is instead dispersive or frequency selective (i.e., different amounts of attenuation at different sub-bands of the system bandwidth). For such a multipath channel, the particular data rate to be used for data transmission may be selected to account for the multipath or frequency selective nature of the channel.

[0026] Each data rate, \( D(r) \), may thus be associated with a set of parameters that characterizes it. These parameters may include the modulation scheme \( M(r) \), the coding rate \( C(r) \), and the required SNR\((r) \), as follows:

\[
D(r) \leftrightarrow [M(r), C(r), \text{SNR}(r)] , \quad \text{Eq (2)}
\]

where \( r \) is an index for the data rates, i.e., \( r = 0, 1, \ldots, N_R - 1 \), where \( N_R \) is the total number of data rates available for use. Expression (2) states that data rate \( D(r) \) may be transmitted using modulation scheme \( M(r) \) and coding rate \( C(r) \) and further requires \( \text{SNR}(r) \) in an AWGN channel to achieve the desired nominal PER \( P_e \). The \( N_R \) data rates may be ordered such that \( D(0) < D(1) < D(2) \ldots < D(N_R - 1) \).

[0027] In accordance with an aspect of the invention, the maximum data rate that may be reliably transmitted over a given multipath channel in an OFDM system is determined based on a metric for an equivalent AWGN channel. Reliable transmission is achieved if the desired PER of \( P_e \) is maintained for the data transmission. Details of this aspect are described below.

[0028] Fig. 1B is a diagram that graphically illustrates the rate selection for a multipath channel using an equivalent channel. For a given multipath channel defined by a channel response of \( H(k) \) and a noise variance of \( N_0 \), the OFDM system may be capable of achieving an equivalent data rate of \( D_{\text{equiv}} \) using modulation scheme \( M(k) \), where \( M(k) \) may be different for different frequency subchannels. This \( D_{\text{equiv}} \) may be estimated as described below based on a particular channel capacity function \( f(H(k), N_0, M(k)) \). Since the bandwidth of each individual frequency subchannel is normalized to 1, it does not appear as an argument of the function \( f \). The metric, which is an estimate of the SNR, \( \text{SNR}_{\text{equiv}} \), required by an equivalent AWGN channel to transmit at the equivalent data rate of \( D_{\text{equiv}} \) using modulation scheme \( M(k) \) at the desired PER of \( P_e \), may be derived for \( D_{\text{equiv}} \) using \( M(k) \) and further based on a function \( g(D_{\text{equiv}}, M(k)) \) that is also described below.

[0029] For a data rate \( D(k) \), modulation scheme \( M(k) \), and coding rate \( C(k) \), the AWGN channel would need an SNR of \( \text{SNR}_{\text{eq}} \) or better to achieve the desired PER of \( P_e \). This threshold \( \text{SNR}_{\text{eq}} \) may be determined by computer simulation or some other means. The data rate \( D(k) \) may then be deemed as being supported by the OFDM system for the multipath channel if the metric (or \( \text{SNR}_{\text{eq}} \)) is equal to or greater than \( \text{SNR}_{\text{eq}} \). As the data rate \( D(k) \) increases, the threshold \( \text{SNR}_{\text{eq}} \) increases for the given channel conditions defined by \( H(k) \) and \( N_0 \). The maximum data rate that may be supported by the OFDM system is thus limited by the channel conditions. Various schemes are provided herein to determine the maximum data rate that may be supported by the OFDM system for the given multipath channel. Some of these schemes are described below.

[0030] In a first rate selection scheme, the metric \( \Psi \) receives a set of parameters for a data transmission on a given multipath channel in an OFDM system and, based on the received parameters, provides an estimate of the SNR for an AWGN channel equivalent to the multipath channel. These input parameters to the metric \( \Psi \) may include one or more parameters related to the processing of the data transmission (e.g., the modulation scheme \( M(k) \)) and one or more parameters related to the communication channel (e.g., the channel response \( H(k) \) and the noise variance \( N_0 \)). As noted above, the modulation scheme \( M(k) \) may be associated with a specific data rate \( D(k) \). The metric \( \Psi \) is the estimate of the SNR of the equivalent AWGN channel (i.e., \( \Psi = \text{SNR}_{\text{equiv}} \)). The maximum data rate supported by the multipath channel may then be determined as the highest data rate associated with an equivalent SNR that is greater than or equal to the threshold SNR, \( \text{SNR}_{\text{eq}} \), required on the AWGN channel to achieve the desired PER of \( P_e \) using the coding and modulation schemes associated with the data rate.

[0031] Various functions may be used for the metric \( \Psi \), some of which are provided below. In an embodiment, the metric \( \Psi \) is defined as:

\[
\Psi = g\left\{ \left[ \sum_{k=0}^{N_R - 1} f[H(k), N_0, M] \right], M \right\} , \quad \text{Eq (3)}
\]

In equation (3), the function \( f[H(k), N_0, M] \) determines the maximum data rate that modulation scheme \( M \) can carry on the \( k \)-th frequency subchannel with the frequency response \( H(k) \) and the noise variance \( N_0 \). The function \( f[H(k), N_0, M] \) may be defined based on various channel capacity functions, as described below.

[0032] The parameters \( H(k) \) and \( N_0 \) may be mapped to an SNR\((k) \). If the total transmit power, \( P_{\text{total}} \), for the system is fixed and the allocation of the transmit power to the \( N_R \) frequency subchannels is uniform and fixed, then the SNR for
each frequency subchannel may be expressed as:

\[ \text{SNR}(k) = \frac{P_{\text{total}} |H(k)|^2}{N_0} \]  

\[ \text{Eq (4)} \]

As shown in equation (4), SNR(k) is a function of the channel response \( H(k) \) and the noise variance \( N_0 \), which are two of the parameters of the function \( f[H(k), N_0, M] \).

The summation in equation (3) is performed for \( f[\cdot] \) over all \( N_F \) frequency subchannels to provide the equivalent data rate \( D_{\text{equiv}} \) that may be transmitted on the AWGN channel. The function \( g(D_{\text{equiv}}, M) \) then determines the SNR needed in the AWGN channel to reliably transmit at the equivalent data rate \( D_{\text{equiv}} \) using the modulation scheme \( M \).

Equation (3) assumes that the same modulation scheme \( M \) is used for all \( N_F \) frequency subchannels in the OFDM system. This restriction results in simplified processing at the transmitter and receiver in the OFDM system but may sacrifice performance.

If different modulation schemes may be used for different frequency subchannels, then the metric \( \Psi \) may be defined as:

\[ \Psi = \sum_{k=0}^{N_F-1} g(f[H(k), N_0, M(k)], M(k)) \]  

\[ \text{Eq (5)} \]

As shown in equation (5), the modulation scheme, \( M(k) \), is a function of the index \( k \) of the frequency subchannels. The use of different modulation schemes and/or coding rates for different frequency subchannels is also referred to as "bit loading".

The function \( f[\cdot] \) determines the data rate that may be reliably transmitted over the AWGN channel for a set of parameters collectively represented as \( x \), where \( x \) may be a function of frequency (i.e., \( x(k) \)). In equation (5), the function \( f[H(k), N_0, M(k)] \), where \( x(k)=[H(k), N_0, M(k)] \), determines the data rate that modulation scheme \( M(k) \) can carry on the \( k \)-th frequency subchannel with the channel response \( H(k) \) and the noise variance \( N_0 \). The function \( g(f[x(k)], M(k)) \) then determines the SNR needed in the equivalent AWGN channel to carry the data rate determined by \( f[x(k)] \). The summation in equation (5) is then performed for \( g(f[x(k)], M(k)) \) over all \( N_F \) frequency subchannels to provide the estimate of the SNR for the equivalent AWGN channel, \( \text{SNR}_{\text{equiv}} \).

The function \( f[\cdot] \) may be defined based on various channel capacity functions or some other functions or techniques. The absolute capacity of a system is typically given as the theoretical maximum data rate that may be reliably transmitted for the channel response \( H(k) \) and the noise variance \( N_0 \). The "constrained" capacity of a system depends on the specific modulation scheme or constellation, \( M(k) \), used for data transmission and is lower than the absolute capacity.

In one embodiment, the function \( f[H(k), N_0, M(k)] \) is defined based on the constrained channel capacity function and may be expressed as:

\[ f(k) = M_k - \frac{1}{2^{M_k}} \sum_{i=1}^{2^{M_k}} \left( \log_2 \sum_{j=1}^{2^{M_k}} \exp\left(-\text{SNR}(k)(|a_i - a_j|^2 + 2\Re\{x^*(a_i - a_j)\})\right) \right) \]  

\[ \text{Eq (6)} \]

where \( M_k \) is related to the modulation scheme \( M(k) \), i.e., the modulation scheme \( M(k) \) corresponds to a \( 2^{M_k} \)-ary constellation (e.g., \( 2^{M_k} \)-ary QAM), where each of the \( 2^{M_k} \) points in the constellation may be identified by \( M_k \) bits; \( a_i \) and \( a_j \) are the points in the \( 2^{M_k} \)-ary constellation; \( x \) is a complex Gaussian random variable with zero mean and a variance of \( 1/\text{SNR}(k) \); and \( E[\cdot] \) is the expectation operation, which is taken with respect to the variable \( x \) in equation (6).
[0040] In another embodiment, the function \( f(x) \) is defined based on the Shannon (or theoretical) channel capacity function and may be expressed as:

\[
f(k) = \log_2[1 + \text{SNR}(k)], \quad \text{Eq} (7)
\]

where \( W \) is the system bandwidth. As shown in equation (7), the Shannon channel capacity is not constrained by any given modulation scheme (i.e., \( M(k) \) is not a parameter in equation (7)).

[0041] The particular choice of function to use for \( f(x) \) may be dependent on various factors, such as the OFDM system design. For a typical system that employs one or more specific modulation schemes, it has been found that the matrix \( \Psi \) defined as shown in equation (3), when used in conjunction with the constrained channel capacity for the function \( f(x) \) as shown in equation (6), is an accurate estimator of the maximum supported data rate for the OFDM system for the AWGN channel as well as for the multipath channel.

[0042] The function \( g(f[x],M(k)) \) determines the SNR needed in the AWGN channel to support the equivalent data rate, which is determined by the function \( f(x) \), using the modulation scheme \( M(k) \). In one embodiment, the function \( g(f[x],M(k)) \) is defined as:

\[
g(f[x],M(k)) = f[x]^{-1}. \quad \text{Eq} (8)
\]

Since the function \( f[x] \) is dependent on the modulation scheme \( M(k) \), the function \( g(f[x],M(k)) \) is also dependent on the modulation scheme. In one implementation, the function \( f[x]^{-1} \) may be derived for each modulation scheme that may be selected for use and may be stored to a respective table. The function \( g(f[x],M(k)) \) may then be evaluated for a given value of \( f[x] \), by accessing the specific table for the modulation scheme \( M(k) \). The function \( g(f[x],M(k)) \) may also be defined using other functions or derived by other means, and this is within the scope of the invention.

[0043] FIG. 2 is a flow diagram of an embodiment of a process 200 for selecting data rate for use in the OFDM system based on the metric \( \Psi \). Initially, the available data rates (i.e., those supported by the OFDM system) are ordered such that \( D(0) < D(1) < \ldots < D(N_{r}-1) \). The highest available data rate is then selected (e.g., by setting a rate variable to the index for the highest data rate, or rate = \( N_{r}-1 \)), at step 212. Various parameters associated with the selected data rate \( D(\text{rate}) \), such as the modulation scheme \( M(\text{rate}) \), are then determined, at step 214. Depending on the design of the OFDM system, each data rate may be associated with one or multiple modulation schemes. Each modulation scheme of the selected data rate may then be evaluated based on the following step. For simplicity, the following assumes that only one modulation scheme is associated with each data rate.

[0044] The metric \( \Psi \) is then evaluated for the specific modulation scheme \( M(\text{rate}) \) associated with the selected data rate \( D(\text{rate}) \), at step 216. This may be achieved by evaluating the function for the metric \( \Psi \), as shown in equation (3), which is:

\[
\Psi = g\left(\sum_{k=0}^{N_{r}-1} f[H(k),N_{0},M(\text{rate})]M(\text{rate})\right).
\]

The metric \( \Psi \) represents an estimate of the SNR needed in the equivalent AWGN channel to reliably transmit the equivalent data rate using the modulation scheme \( M(\text{rate}) \).

[0045] The threshold SNR, \( \text{SNR}_{\text{th}}(\text{rate}) \), needed to transmit the selected data rate \( D(\text{rate}) \) with the desired PER of \( P_{e} \) in the AWGN channel is then determined, at step 218. The threshold SNR \( \text{SNR}_{\text{th}}(\text{rate}) \) is a function of the modulation scheme \( M(\text{rate}) \) and the coding rate \( C(\text{rate}) \) associated with the selected data rate. The threshold SNR may be determined for each of the possible data rates via computer simulation or by some other means, and may be stored for later use.

[0046] A determination is then made whether or not the metric \( \Psi \) is greater than or equal to the threshold SNR \( \text{SNR}_{\text{th}}(\text{rate}) \) associated with the selected data rate, at step 220. If the metric \( \Psi \) is greater than or equal to \( \text{SNR}_{\text{th}}(\text{rate}) \), which indicates that the SNR achieved by the OFDM system for the data rate \( D(\text{rate}) \) in the multipath channel is sufficient to achieve the desired PER of \( P_{e} \), then that data rate is selected for use, at step 224. Otherwise, the next lower available data rate is selected for evaluation (e.g., by decrementing the rate variable by one, or rate = rate-1), at step 222. The next lower data rate is then evaluated by returning to step 214. Steps 214 through 222 may be repeated as often as needed until the maximum supported data rate is identified and provided in step 222.

[0047] The metric \( \Psi \) is a monotonic function of data rate and increases with increasing data rate. The threshold SNR is also a monotonic function that increases with increasing data rate. The embodiment shown in FIG. 2 evaluates the available data rates, one at a time, from the maximum available data rate to the minimum available data rate. The highest
data rate associated with a threshold SNR, $\text{SNR}_{\text{equiv}}(r)$, that is smaller than or equal to the metric $\Psi$ is selected for use.

[0048] In another embodiment, the metric $\Psi$ may be evaluated for a particular modulation scheme $M(r)$ to derive an estimate of the SNR for the equivalent AWGN channel, $\text{SNR}_{\text{equiv}}(r)$. The maximum data rate, $D_{\text{max}}(r)$, supported by the AWGN channel for the desired PER at this equivalent SNR using the modulation scheme $M(r)$ is then determined (e.g., via a look-up table). The actual data rate to be used in the OFDM system for the multipath channel may then be selected to be less than or equal to the maximum data rate, $D_{\text{max}}(r)$, supported by the AWGN channel.

[0049] In a second rate selection scheme, the metric $\Psi$ is defined as a post-detection SNR achieved for the multipath channel by a single carrier system after equalization. The post-detection SNR is representative of the ratio of the total signal power to the noise plus interference after equalization at the receiver. Theoretical values of post-detection SNR achieved in the single carrier system with equalization may be indicative of the performance of an OFDM system, and therefore may be used to determine the maximum supported data rate in the OFDM system. Various types of equalizer may be used to process the received signal in the single carrier system to compensate for distortions in the received signal introduced by the multipath channel. Such equalizers may include, for example, a minimum mean square error linear equalizer (MMSE-LE), a decision feedback equalizer (DFE), and others.

[0050] The post-detection SNR for an (infinite-length) MMSE-LE may be expressed as:

$$\text{SNR}_{\text{mmse-le}} = \frac{1 - J_{\text{min}}}{J_{\text{min}}} ,$$

where $J_{\text{min}}$ is given by

$$J_{\text{min}} = \frac{T}{2\pi} \int_{-\pi/T}^{\pi/T} X(\omega) + N_0 d\omega ,$$

where $X(\omega)$ is the folded spectrum of the channel transfer function $H(f)$.

[0051] The post-detection SNR for an (infinite-length) DFE may be expressed as:

$$\text{SNR}_{\text{df}} = \exp \left[ \frac{T}{2\pi} \int_{-\pi/T}^{\pi/T} \ln \left( \frac{X(\omega) + N_0}{N_0} \right) d\omega \right] - 1 .$$

The post-detection SNRs for the MMSE-LE and DFE shown in equations (9) and (10), respectively, represent theoretical values. The post-detection SNRs for the MMSE-LE and DFE are also described in further detail by J. G. Proakis, in a book entitled "Digital Communications", 3rd Edition, 1995, McGraw Hill, sections 10-2-2 and 10-3-2, respectively, which are incorporated herein by reference.

[0053] Post-detection SNRs, such as those described by the analytical expressions shown in equations (9) and (10), may be determined for the multipath channel and used as an estimate of the metric $\Psi$ (i.e., $\Psi = \text{SNR}_{\text{mmse-le}}$ or $\Psi = \text{SNR}_{\text{df}}$). The post-detection SNR (e.g., $\text{SNR}_{\text{mmse-le}}$ or $\text{SNR}_{\text{df}}$) for the equivalent AWGN channel may be compared against the threshold SNR, $\text{SNR}_{\text{th}}$, for the desired PER $P_e$. The data rate that may be used in the OFDM system for the multipath channel may be determined using this comparison.

[0054] The metric $\Psi$ may also be defined based on some other functions, and the equivalent data rate may also be estimated based on some other techniques, and this is within the scope of the invention.

[0055] The data rate selected for use in the OFDM system based on the metric $\Psi$ represents a prediction of the data rate that may be supported by the multipath channel for the desired PER of $P_e$. As with any rate prediction scheme, there will inevitably be prediction errors. In order to ensure that the desired PER can be achieved, the prediction errors may be estimated and a back-off factor may be used in determining the data rate that can be supported by the multipath channel. This back-off reduces the throughput of the OFDM system. Thus, it is desirable to keep this back-off as small as possible while still achieving the desired PER.
In accordance with another aspect of the invention, an incremental transmission (IT) scheme is provided and may be advantageously used in conjunction with the rate selection of the first aspect to reduce the amount of back-off and to improve system throughput. The IT scheme transmits a given packet using one or more discrete transmissions, one transmission at a time and up to a particular limit. The first transmission for the packet includes sufficient amount of data such that the packet can be recovered error-free at the receiver based on the expected channel conditions. However, if the first transmission is excessively degraded by the communication channel such that error-free recovery of the packet is not achieved, then an incremental transmission of an additional amount of data for the packet is performed. The receiver then attempts to recover the packet based on the additional data in the incremental transmission and all data previously received for the packet. The incremental transmission by the transmitter and the decoding by the receiver may be attempted for one or more times, until the packet is recovered error-free or the maximum number of incremental transmissions is reached.

An embodiment of the IT scheme may be implemented as follows. First, the data for a packet is coded using a lower coding rate (for a forward error correction code) than the coding rate that may be used for the packet without any incremental transmission. Next, some of the coded bits for the packet are punctured and only a subset of all the coded bits is transmitted for the first transmission of the packet. If the packet is correctly received, then the receiver may send back an acknowledgement (ACK) indicating that the packet was received error-free. Alternatively, the receiver may send back a negative acknowledgement (NACK) if it receives the packet in error.

In either case, if the acknowledgement is not received by the transmitter for the packet or a negative acknowledgement is received, then the transmitter sends an incremental packet to the receiver. This incremental packet may include some of the original punctured coded bits that were not sent in the first transmission. The receiver then attempts to decode the packet by using the coded bits sent in both the first transmission as well as the second transmission. The additional coded bits from the second transmission provide more energy and improve the error correction capability. One or more incremental transmissions may be performed, typically one at a time until the acknowledgement is received or the negative acknowledgement is not received.

If incremental transmission is employed by the system, then a smaller back-off may be used to account for rate prediction errors and more aggressive rate selections may be made. This may result in improved system throughput.

The incremental transmission in combination with the rate selection described above also provides an efficient mechanism for determining the maximum data rate supported by fixed or slow-varying communication channels. Consider a fixed-access application where the multipath profile of the channel changes slowly. In this case, an initial data rate may be selected based on the techniques described above and used for data transmission. If the initial data rate is higher than the channel can support, then the IT scheme can transmit additional coded bits until the packet can be correctly decoded at the receiver. The maximum data rate that the channel can support may then be determined based on the total number of coded bits sent in the first transmission and any subsequent incremental transmissions. If the channel changes slowly, then the determined data rate may be used until the channel changes, at which time a new data rate may be determined.

The incremental transmission thus provides numerous advantages. First, the use of incremental transmission allows for an aggressive data rate selection to increase system throughput. Second, incremental transmission provides a means for remedying prediction errors that inevitably arise for any rate prediction scheme (with the frequency and magnitude of the prediction errors being dependent on the amount of back-off employed). And third, incremental transmission provides a mechanism to more accurately determine the maximum supported data rate for fixed or slow-varying channels.

FIG. 3 is a block diagram of an embodiment of a transmitter system 110a and a receiver system 150a, which are capable of implementing various aspects and embodiments of the invention.

At transmitter system 110a, traffic data is provided at a particular data rate from a data source 308 to a transmit (TX) data processor 310, which formats, interleaves, and codes the traffic data based on a particular coding scheme to provide coded data. The data rate and the coding may be determined by a data rate control and a coding control, respectively, provided by a controller 330.

The coded data is then provided to a modulator 320, which may also receive pilot data (e.g., data of a known pattern and processed in a known manner, if at all). The pilot data may be multiplexed with the coded traffic data, e.g., using time division multiplex (TDM) or code division multiplex (CDM), in all or a subset of the frequency subchannels used to transmit the traffic data. In a specific embodiment, for OFDM, the processing by modulator 320 includes (1) modulating the received data with one or more modulation schemes, (2) transforming the modulated data to form OFDM symbols, and (3) appending a cyclic prefix to each OFDM symbol to form a corresponding transmission symbol. The modulation is performed based on a modulation control provided by controller 330. The modulated data (i.e., the transmission symbols) is then provided to a transmitter (TMTR) 322.

Transmitter 322 converts the modulated data into one or more analog signals and further conditions (e.g., amplifies, filters, and quadrature modulates) the analog signals to generate a modulated signal suitable for transmission over the communication channel. The modulated signal is then transmitted via an antenna 324 to the receiver system.
At receiver system 150a, the transmitted modulated signal is received by an antenna 352 and provided to a receiver (RcvR) 354. Receiver 354 conditions (e.g., filters, amplifies, and downconverts) the received signal and digitizes the conditioned signal to provide data samples. A demodulator (Demod) 360 then processes the data samples to provide demodulated data. For OFDM, the processing by demodulator 360 may include (1) removing the cyclic prefix previously appended to each OFDM symbol, (2) transforming each recovered OFDM symbol, and (3) demodulating the recovered modulation symbols in accordance with one or more demodulation schemes complementary to the one or more modulation schemes used at the transmitter system.

A receive (RX) data processor 362 then decodes the demodulated data to recover the transmitted traffic data. The processing by demodulator 360 and RX data processor 362 is complementary to that performed by modulator 320 and TX data processor 310, respectively, at transmitter system 110a.

As shown in FIG. 3, demodulator 360 may derive estimates of the channel response, $\hat{H}(k)$, and provide these estimates to a controller 370. RX data processor 362 may also derive and provide the status of each received packet and may further provide one or more other performance metrics indicative of the decoded results. Based on the various types of information received from demodulator 360 and RX data processor 362, controller 370 may determine or select a particular rate for the data transmission based on the techniques described above. Feedback information in the form of a selected rate, the channel response estimates, ACK/NACK for the receive packet, and so on, may be provided by controller 370, processed by a TX data processor 378, modulated by a modulator 380, and conditioned and transmitted by a transmitter 354 back to transmitter system 110a.

At transmitter system 110a, the modulated signal from receiver system 150a is received by antenna 324, conditioned by a receiver 322, and demodulated by a demodulator 340 to recover the feedback information transmitted by the receiver system. The feedback information is then provided to controller 330 and used to control the processing of the data transmission to the receiver system. For example, the data rate of the data transmission may be determined based on the selected rate provided by the receiver system, or may be determined based on the channel response estimates from the receiver system. The specific coding and modulation schemes associated with the selected rate are determined and reflected in the coding and modulation control provided to TX data processor 310 and modulator 320. The received ACK/NACK may be used to initiate an incremental transmission (not shown in FIG. 3 for simplicity).

Controllers 330 and 370 direct the operation at the transmitter and receiver systems, respectively. Memories 332 and 372 provide storage for program codes and data used by controllers 330 and 370, respectively.

FIG. 4 is a block diagram of a transmitter unit 400, which is an embodiment of the transmitter portion of transmitter system 110a. Transmitter unit 400 includes (1) a TX data processor 310a that receives and processes traffic data to provide coded data and (2) a modulator 320a that modulates the coded data to provide modulated data. TX data processor 310a and modulator 320a are one embodiment of TX data processor 310 and modulator 320, respectively, in FIG. 3.

In the specific embodiment shown in FIG. 4, TX data processor 310a includes an encoder 412, a channel interleaver 414, and a puncturer 416. Encoder 412 receives and codes the traffic data in accordance with one or more coding schemes to provide coded bits. The coding increases the reliability of the data transmission. Each coding scheme may include any combination of CRC coding, convolutional coding, Turbo coding, block coding, and other coding, or no coding at all. The traffic data may be partitioned into packets (or frames), and each packet may be individually processed and transmitted. In an embodiment, for each packet, the data in the packet is used to generate a set of CRC bits, which is appended to the data, and the data and CRC bits are then coded with a convolutional code or a Turbo code to generate the coded data for the packet.

Channel interleaver 414 then interleaves the coded bits based on a particular interleaving scheme to provide diversity. The interleaving provides time diversity for the coded bits, permits the data to be transmitted based on an average SNR for the frequency subchannels used for the data transmission, combats fading, and further removes correlation between coded bits used to form each modulation symbol. The interleaving may further provide frequency diversity if the coded bits are transmitted over multiple frequency subchannels.

Puncturer 416 then punctures (i.e., deletes) zero or more of the interleaved coded bits and provides the required number of unpunctured coded bits to modulator 320a. Puncturer 416 may further provide the punctured coded bits to a buffer 418, which stores these coded bits in case they are needed for an incremental transmission at a later time, as described above.

In the specific embodiment shown in FIG. 4, modulator 320a includes a symbol mapping element 422, an IFFT 424, and a cyclic prefix generator 426. Symbol mapping element 422 maps the multiplexed pilot data and coded traffic data to modulation symbols for one or more frequency subchannels used for data transmission. One or more modulation schemes may be used for the frequency subchannels, as indicated by the modulation control. For each modulation scheme selected for use, the modulation may be achieved by grouping sets of received bits to form multi-bit symbols and mapping each multi-bit symbol to a point in a signal constellation corresponding to the selected modulation scheme (e.g., QPSK, M-PSK, M-QAM, or some other scheme). Each mapped signal point corresponds to a modulation symbol. Symbol mapping element 422 then provides a vector of (up to Np) modulation symbols for each transmission symbol.
period, with the number of modulation symbols in each vector corresponding to the number of (up to \( N_F \)) frequency subchannels selected for use for that transmission symbol period.

Noise variance \( \Psi(\theta) \) and the noise variance, \( N_0 \), and to provide these estimates to controller 370. The channel response and noise variance may be estimated based on the received data samples for the pilot symbols (e.g., based on the FFT coefficients from FFT 512 for the pilot symbols).

Controller 370 may be designed to implement various aspects and embodiments of the rate selection and the signaling for the incremental transmission. For the rate selection, controller 370 may determine the maximum data rate that may be used for the given channel conditions based on the metric \( \Psi(\theta) \), as described above. For incremental transmission, controller 370 may provide an ACK or a NACK for each received transmission for a given packet, which may be used at the transmitter system to transmit an additional portion of the packet if the packet cannot be recovered correctly at the receiver system.

FIGS. 1A and 3 show a simple design whereby the receiver sends back the rate for the data transmission. Other designs may also be implemented and are within the scope of the invention. For example, the channel estimates
may be sent to the transmitter (instead of the rate), which may then determine the rate for the data transmission based
on the received channel estimates.

[0086] The rate selection and incremental transmission techniques described herein may be implemented using various
designs. For example, channel estimator 516 in FIG. 5 used to derive and provide the channel estimates may be
implemented by various elements in the receiver system. Some or all of the processing to determine the rate may be
performed by controller 370 (e.g., with one or more look-up tables stored in memory 372). Other designs for performing
the rate selection and incremental transmission may also be contemplated and are within the scope of the invention.

[0087] The rate selection and incremental transmission techniques described herein may be implemented by various
means. For example, these techniques may be implemented in hardware, software, or a combination thereof. For a
hardware implementation, some of the elements used to implement the rate selection and/or incremental transmission
may be implemented within one or more application specific integrated circuits (ASICs), digital signal processors (DSPs),
digital signal processing devices (DSPDs), programmable logic devices (PLDs), field programmable gate arrays (FPGAs),
processors, controllers, micro-controllers, microprocessors, other electronic units designed to perform the functions
described herein, or a combination thereof.

[0088] For a software implementation, some portions of the rate selection and/or incremental transmission may be
implemented with modules (e.g., procedures, functions, and so on) that perform the functions described herein. The
software codes may be stored in a memory unit (e.g., memory 332 or 372 in FIG. 3) and executed by a processor (e.g.,
controller 330 or 370). The memory unit may be implemented within the processor or external to the processor, in which
case it can be communicatively coupled to the processor via various means as is known in the art.

[0089] The previous description of the disclosed embodiments is provided to enable any person skilled in the art to
make or use the present invention. Various modifications to these embodiments will be readily apparent to those skilled
in the art, and the generic principles defined herein may be applied to other embodiments without departing from the
spirit or scope of the invention. Thus, the present invention is not intended to be limited to the embodiments shown
herein but is to be accorded the widest scope consistent with the principles and novel features disclosed herein.

Further Embodiments

[0090] According to a further embodiment of the present invention, there is provided a method for determining a data
rate for a data transmission over a communication channel in a wireless communication system, comprising:

identifying a set of parameters for the data transmission;
estimating one or more characteristics of the communication channel;
deriving a metric for an equivalent channel based on the set of parameters and the one or more estimated channel
characteristics;
determining a threshold signal quality required for the equivalent channel to support a particular data rate; and
indicating whether or not the particular data rate is supported by the communication channel based on the metric
and the threshold signal quality.

[0091] The set of parameters may include a particular coding scheme and a particular modulation scheme to be used
for the data transmission.

[0092] The one or more estimated channel characteristics may include an estimated frequency response of the com-
munication channel and an estimated noise variance of the communication channel.

[0093] The equivalent channel may have a flat frequency response across a system bandwidth.

[0094] The deriving the metric may include determining an equivalent data rate for the equivalent channel based on
a first function, the set of parameters, and the one or more estimated channel characteristics,
and determining a threshold signal quality required for the equivalent channel to support a particular data rate; and
indicating whether or not the particular data rate is supported by the communication channel based on the metric
and the threshold signal quality.

[0096] The signal quality may be quantified by a signal-to-noise-and-interference ratio (SNR).

[0097] The deriving the metric may include estimating a post-detection SNR for the communication channel based on
a particular equalizer, and wherein the estimated signal quality for the equivalent channel is the estimated post-detection
SNR.

[0098] Preferably, a single modulation scheme is used for all frequency subchannels used for the data transmission.

[0099] Preferably a plurality of modulation schemes are used for a plurality of frequency subchannels used for the
data transmission.

[0100] The wireless communication system may be an orthogonal frequency division multiplex (OFDM) system.

[0101] According to a further embodiment of the present invention, there is provided a method for determining a rate
for a data transmission over a communication channel in an orthogonal frequency division multiplex (OFDM) system,
comprising:

identifying a set of parameters for a particular rate and indicative of a particular data rate, a particular modulation scheme, and a particular coding scheme;
estimating and one or more characteristics of the communication channel;
deriving an equivalent data rate based on a first function, the set of parameters, and the one or more estimated channel characteristics;
deriving a metric for the equivalent channel based on a second function, the equivalent data rate, and the particular modulation scheme;
determining a threshold signal-to-noise-and-interference ratio (SNR) required for the equivalent channel to support the particular data rate with the particular modulation and coding schemes; andindicating the particular rate as being supported by the communication channel if the metric is greater than or equal to the threshold SNR.

[0102] The first function may be a constrained channel capacity function.
[0103] The first function may be the Shannon channel capacity function.
[0104] The particular rate may be selected from among a set of available rates, and wherein each of one or more available rates may be evaluated to determine a highest data rate supported by the communication channel.
[0105] The deriving the equivalent data rate and the deriving the metric may be both achieved by estimating a post-detection SNR for the communication channel after equalization by a particular equalizer.
[0106] The particular equalizer may be a minimum mean square error linear equalizer (MMSE-LE) or a decision feedback equalizer (DFE).
[0107] According to a further embodiment of the present invention, there is provided a method for transmitting data over a communication channel in an orthogonal frequency division multiplex (OFDM) system, comprising:

identifying an initial rate to be used for a data transmission over the communication channel;
processing data for transmission over the communication channel based on the initial rate;
transmitting a first portion of the processed data;
receiving an indication of incorrect reception of the data transmission; and
transmitting an additional portion of the processed data.

[0108] The initial rate may be determined based on an estimated signal-to-noise-and-interference ratio (SNR) for an equivalent channel.
[0109] The initial rate may be indicative of a particular data rate, a particular modulation scheme, and a particular coding scheme to be used for the data transmission.
[0110] The processing may include:
coding the data in accordance with the particular coding scheme;
puncturing the coded data in accordance with a particular puncturing scheme; and
modulating unpunctured coded data in accordance with the particular modulation scheme.

[0111] The first portion may comprise the unpunctured coded data and the additional portion comprises the coded data previously punctured and not yet transmitted.
[0112] The method may further comprise repeating the transmission of an additional portion, one or more times, until an indication of correct reception of the data transmission is received.
[0113] Preferably each additional portion to be transmitted in response to receiving the indication of incorrect reception comprises processed data not transmitted previously.
[0114] According to a further embodiment of the present invention, there is provided a receiver unit in a wireless communication system, comprising:
a channel estimator operative to derive estimates of one or more characteristics of a communication channel used for a data transmission; and
a rate selector operative to receive channel estimates from the channel estimator and a set of parameters indicative of a particular rate for the data transmission, derive a metric for an equivalent channel, determine a threshold signal quality required for the equivalent channel to support the particular rate, and indicate whether or not the particular rate is supported by the communication channel based on the metric and the threshold signal quality.

[0115] The receiver unit may further comprise:
a decoder operative to provide a status of each received transmission for a particular packet of data; and a controller operative to provide feedback information comprised of the particular rate and an indication of the packet status.

The rate selector may be further operative to determine an equivalent data rate for the equivalent channel based on a first function, the set of parameters, and the channel estimates, and to derive the metric for the equivalent channel based on a second function, the equivalent data rate, and a particular modulation scheme associated with the particular rate.

The first function may be a constrained channel capacity function.

According to a further embodiment of the present invention, there is provided a receiver apparatus in a wireless communication system, comprising:

means for deriving estimates of one or more characteristics of a communication channel used for a data transmission;
means for deriving a metric for an equivalent channel based on the channel estimates and a set of parameters indicative of a particular rate for the data transmission;
means for determining a threshold signal quality required for the equivalent channel to support the particular rate; and means for indicating whether or not the particular rate is supported by the communication channel based on the metric and the threshold signal quality.

The receiver apparatus may further comprise means for determining an equivalent data rate for the equivalent channel based on a first function, the set of parameters, and the channel estimates, and wherein the metric is derived based on a second function, the equivalent data rate, and a particular modulation scheme associated with the particular rate.

The receiver apparatus may further comprise means for storing one or more tables for the first function.

According to a further embodiment of the present invention, there is provided a transmitter unit in an orthogonal frequency division multiplex (OFDM) system, comprising:

a controller operative to identify an initial rate to be used for a data transmission over a communication channel and to receive an indication of correct or incorrect reception of the data transmission, wherein the initial rate is indicative of a particular data rate, a particular modulation scheme, and a particular coding scheme to be used for the data transmission;
a transmit data processor operative to code data in accordance with the particular coding scheme;
a modulator operative to modulate a first portion of the coded data in accordance with the particular modulation scheme, and to further modulate an additional portion of the coded data if the indication of incorrect reception of the data transmission is received; and
a transmitter operative to transmit the modulated data.

Means for identifying an initial rate to be used for a data transmission over a communication channel, wherein the initial rate is indicative of a particular data rate, a particular modulation scheme, and a particular coding scheme to be used for the data transmission means for coding data in accordance with the particular coding scheme;
means for modulating a first portion of the coded data in accordance with the particular modulation scheme;
means for receiving an indication of correct or incorrect reception of the data transmission at a receiver;
means for modulating an additional portion of the coded data if the indication of incorrect reception of the data transmission is received; and
means for transmitting the modulated data.

According to a further embodiment of the present invention, there is provided a transmitter apparatus in a wireless communication system, comprising:

a controller operative to identify an initial rate to be used for a data transmission over a communication channel, wherein the initial rate is indicative of a particular data rate, a particular modulation scheme, and a particular coding scheme to be used for the data transmission;
means for modulating a first portion of the coded data in accordance with the particular modulation scheme;
means for receiving an indication of correct or incorrect reception of the data transmission at a receiver;
means for modulating an additional portion of the coded data if the indication of incorrect reception of the data transmission is received; and
means for transmitting the modulated data.

Claims

1. A method for transmitting data over a communication channel in an orthogonal frequency division multiplex, OFDM, system, comprising:
identifying an initial rate to be used for a data transmission over the communication channel;
processing data for transmission over the communication channel based on the initial rate;
transmitting a first portion of the processed data;
receiving an indication of incorrect reception of the data transmission; and
transmitting an additional portion of the processed data;
wherein each additional portion to be transmitted in response to receiving the indication of incorrect reception comprises processed data not transmitted previously.

2. The method of claim 1, wherein the initial rate is determined based on an estimated signal-to-noise-and-interference ratio, SNR, for an equivalent channel.

3. The method of claim 1, wherein the initial rate is indicative of a particular data rate, a particular modulation scheme, and a particular coding scheme to be used for the data transmission.

4. The method of claim 3, wherein the processing includes coding the data in accordance with the particular coding scheme; puncturing the coded data in accordance with a particular puncturing scheme; and modulating unpunctured coded data in accordance with the particular modulation scheme.

5. The method of claim 4, wherein the first portion comprises the unpunctured coded data and the additional portion comprises the coded data previously punctured and not yet transmitted.

6. The method of claim 1, further comprising:

repeating the transmission of an additional portion, one or more times, until an indication of correct reception of the data transmission is received.

7. A transmitter apparatus (110, 400) for a wireless communication system, the transmitter apparatus comprising:
means for identifying an initial rate to be used for a data transmission over a communication channel;
means for processing data for transmission over the communication channel based on the initial rate;
means for transmitting a first portion of the processed data;
means for receiving an indication of incorrect reception of the data transmission; and
means for transmitting an additional portion of the processed data;
wherein each additional portion to be transmitted in response to receiving the indication of incorrect reception comprises processed data not transmitted previously.

8. The transmitter apparatus (110, 400) of claim 7, wherein the means for identifying is configured to identify the initial rate based on an estimated signal-to-noise-and-interference ratio, SNR, for an equivalent channel.

9. The transmitter apparatus (110, 400) of claim 7, wherein the initial rate is indicative of a particular data rate, a particular modulation scheme, and a particular coding scheme to be used for the data transmission.

10. The transmitter apparatus (110, 400) of claim 9, wherein the means for processing includes means for coding the data in accordance with the particular coding scheme; means for puncturing the coded data in accordance with a particular puncturing scheme; and means for modulating unpunctured coded data in accordance with the particular modulation scheme.

11. The transmitter apparatus (110, 400) of claim 10, wherein the first portion comprises the unpunctured coded data and the additional portion comprises the coded data previously punctured and not yet transmitted.

12. The transmitter apparatus of (110, 400) claim 7, further comprising:

means for repeating the transmission of an additional portion, one or more times, until an indication of correct reception of the data transmission is received.

13. A transmitter unit (110, 400) for an orthogonal frequency division multiplex, OFDM, system in accordance with claim 7, the transmitter unit comprising:
a controller (330) configured to identify the initial rate to be used for the data transmission over the communication channel and to receive the indication of correct or incorrect reception of the data transmission;
a processor (310) to process data for transmission over the communication channel based on the initial rate;
a transmitter (322) to transmit the first portion of the processed data and to transmit the additional portion of the processed data;
wherein each additional portion to be transmitted in response to receiving the indication of incorrect reception comprises processed data not transmitted previously.
FIG. 1A
