HUMAN ANTI-INFLAMMATORY PHOSPHOLIPASE INHIBITOR PROTEIN

Cloning and expression of the gene encoding human phospholipase inhibitory protein (hPPIP) permits production of an anti-inflammatory protein in practical quantities using recombinant techniques.

HUMAN ANTI-INFLAMMATORY
PHOSPHOLIPASE INHIBITOR PROTEIN

Technical Field

The invention relates to the field of treating inflammation in humans and animals. More particularly, the invention concerns a pure preparation of a phospholipase inhibitory protein (PIP) which is effective in controlling inflammation.

Background Art

The general physiological phenomenon of inflammation at the site of a wound or infection has been recognized for centuries. It is also well understood that while this phenomenon may be of positive value in response to such stimuli, the extent of this response must often be controlled in order properly to secure the comfort of the human or animal subject. In addition, inflammation may occur as a chronic inflammatory disorder, such as, for example, rheumatoid arthritis or systemic lupus erythematosus. Such conditions are debilitating in themselves and can result in often life threatening, acute episodes. The inflammation associated with another such disorder, asthma, may also result in death due to constriction of the bronchia.

Within the last few decades a more detailed picture of the biochemical events associated with inflammation has been accumulated. The picture is a complex one. Part of the initiation process is mediated by peptide kinins, such as bradykinin, which are liberated by kallikrein proteases upon tissue destruction. The kinins or other peptide messengers, act on specific cell receptors at the inflammation site.
to activate the phospholipase enzymes A2 and/or C, to initiate the arachidonate cascade.

The "arachidonate cascade" is of singular importance in maintaining the inflammatory response. Within this complex of reactions, illustrated in Figure 1, arachidonic acid is liberated from membrane phospholipids of a subject cell, and converted to a variety of products known collectively as eicosanoids. The eicosanoids include the leukotrienes and prostaglandins, which are released into the extracellular environment to exert their effects directly on the inflammatory site. They have relatively short half lives. However, their physiological effects are varied and dramatic, and include vasodilation (e.g., prostacyclin and leukotrienes LTC₄ and LTD₄), vasoconstriction (e.g., thromboxane and LTB₄), and histamine release.

Most of the members of the current repertoire of anti-inflammatory pharmaceuticals are directed against some aspect of the arachidonate cascade. From this standpoint, the significant features of the cascade, as shown in Figure 1, are that production of all products begins with the liberation of arachidonic acid from cellular phospholipids, catalyzed by the phospholipases, and the reaction pathway then branches into several reaction series: the cyclooxygenase pathways which generate the prostaglandins and the lipoxygenase pathways which generate leukotrienes. Most of the commonly used non-steroid anti-inflammatory drugs, such as aspirin or indomethacin, inhibit cyclooxygenase, and hence only some of the pathways by which arachidonic acid is converted to end products. Other pathways of the arachidonate cascade are not affected. Steroid, or
glucocorticoid, hormones, on the other hand, generally exert their effect on the production of arachidonic acid from the phospholipid membrane sources, and thus directly effect the entire cascade. Hong, S., et al, Proc Natl Acad Sci (USA) (1976) 73:1730-1734. However, the disadvantages of steroid therapy are well known. Side effects such as water retention, hyperglycemia, hyperlipidemia, osteoporosis, glaucoma, and increased risk of coronary and large-vessel atherosclerosis are among the undesirable responses which may accompany such treatment.

sequencing of rat lipocortin, and the cloning of its human analog, which is a PA2 inhibitor in vitro.

Direct administration of the proteins which inhibit arachidonic acid formation rather than of the glucocorticoids, which stimulate the production of these proteins, would result in the advantages of steroid control of inflammation without exposing the subject to the risk of the attendant side effects. However, the human form of this protein is not available in purified form. It would, of course, be highly desirable to have pure human phospholipase inhibiting protein (PIP) in sufficient purity and amount to permit such direct treatment of unwanted inflammatory response.

Disclosure of the Invention

The invention provides purified human phospholipase inhibitory protein (hPIP) and materials useful in its production by recombinant technology. A material purified to apparent homogeneity from human peritoneal dialysis fluid having a single 40 kd band on SDS-PAGE contains substantial amounts of apolipoprotein IV (apoAIV) and significant PIP activity. Immunization of rabbits with protein eluted from this 40 kd band raises antisera capable of reacting both with apoAIV and with PIP. These antibodies are thus appropriate for screening recombinant and other cells for hPIP production.

Human PIP free from other proteins normally in association with it is obtained in two ways, by direct purification from peritonyl dialysis fluid, and by production using recombinant hosts. Accordingly, in one aspect, the invention relates to human PIP in substantially pure form. In another aspect, the invention relates to a protein having human PIP activity
which comprises the amino acid sequence set forth in Figure 13. In still another aspect, the invention relates to a process for the preparation of purified hPIP from peritoneal dialysis fluid and to the product of that process. The product of the purification process is characterized by a 36 kd or 40 kd molecular weight in the nonglycosylated or glycosylated form, respectively, and by PIP activity.

Pure hPIP may also be produced using recombinant techniques. Accordingly, other aspects of the invention relate to this recombinantly produced hPIP in both nonglycosylated and glycosylated form, to expression systems which permit production of this protein in recombinant hosts, to vectors containing the expression system, to hosts transformed with the system and to a method of producing hPIP by culturing recombinant host cells.

In still other aspects, the invention relates to the antibodies produced in response to administration of the 40 kd mixture of apoAIV and PIP and of the PIP protein of the invention itself, to pharmaceutical compositions containing PIP, and to methods for ameliorating inflammation in human and veterinary subjects using such compositions or purified PIP. It appears that PIP may be stabilized by the presence of apoAIV, and compositions containing PIP in admixture with apoAIV are specifically useful as pharmaceuticals.

Brief Description of the Drawings

Figure 1 shows the arachidonate cascade and the eicosanoid products of the reaction scheme.

Figure 23 displays the relative abilities of purified hPIP and dexamethasone (200 µg), when administered to rats intramuscularly, to inhibit joint swelling associated with adjuvant induced arthritis.

Modes of Carrying Out the Invention

A. Nature of the PIP Protein

The protein of the invention has been prepared using as a starting material, human peritoneal dialysis fluid obtained from dialysis patients. A purification procedure is presented whereby the protein has been obtained in homogeneous form, free of impurities normally associated with the protein as found in its native state. While the purification procedure is successful in obtaining this protein in sufficient purity to be used therapeutically per se, the
availability of the purified material is also a significant step in the development of alternative modes of preparation. Recombinant techniques for the preparation of hPIP are described herein. Accordingly, the PIP of the invention includes not only the hPIP prepared as herein described, but proteins of substantially similar structure obtained using alternative approaches. By "substantially similar" is meant that the activity of the protein in inhibiting phospholipase A2 (PA2 inhibition assay), as described in the in vitro enzymatic assay procedure set forth hereinbelow, is retained. The amino acid sequence set forth in Figure 13 is known to exhibit this activity.

It is well recognized that amino acid sequences may be modified in various ways and still retain their fundamental activity. First, certain portions of the peptide sequence are often not essential for activity, and only a fragment of the entire natively produced protein may be required. Therefore, portions of the amino acid sequence shown in Figure 13 are therefore included within the definition if activity is retained. Second, addition, deletion, or alteration of a particular, or a few particular, amino acids in the sequence, may result in changes which are inconsequential with regard to functionality. Third, since proteins contain ionizable hydrogen, the ionization state of the protein as neutral or salt form, is dependent on the pH of the surrounding medium, if the protein is in solution, or on the pH of the solution from which the protein is prepared in solid form. In addition, the amino acids of the sequence may undergo minor alterations in their side chains, such as, for example, oxidation of sulfhydryl groups, which modifications may also be ineffective in destroying
activity. Finally, proteins are often found in their native states in association with non-protein residues, such as, for example, phosphate, acetyl groups, or carbohydrates. The purified or recombinant PIP protein of the invention is defined functionally, but all embodiments are expected to retain extensive primary sequence homology with the hPIP exemplified in Figure 13. The level of homology is expected to be above 40% considering both conservative changes and exact homologies in the region of interest encoded by nucleotides 490-852 of Figure 13. Additional variation is acceptable in other regions of the protein. All of the foregoing modifications are within the definition so long as the activity as exhibited in the in vitro phospholipase A2 (PA2) inhibition assay, set forth hereinbelow, is not destroyed.

"Active PIP fragment" refers to a peptide comprising, with respect to PIP, only the sequence encoded by the above-mentioned nucleotides 490-852 of Figure 13. If only this fragment is used, somewhat less than 40% homology in the primary structure is required when the secondary structure is sufficiently similar, as determined by application of the standard algorithms of Chou-Fasman or Kyte-Doolittle. In particular the peptide encoded by nucleotides designated 31-381 in the lipocortin disclosed by Wallner et al (supra) provides a secondary structure filling this requirement, though the primary amino acid sequence clearly has less than 40% homology in this region. Therefore, this particular fragment is also claimed, as well as those derived from the hPIP sequence disclosed herein.

"Operably linked" refers to a juxtaposition wherein the components are configured so as to perform their usual function. Thus, control sequences operably
linked to coding sequences are capable of effecting the expression of the coding sequence.

"Control sequence" refers to a DNA sequence or sequences which are capable, when properly ligated to a desired coding sequence, of effecting its expression in hosts compatible with such sequences. Such control sequences include promoters in both procaryotic and eucaryotic hosts, and in procaryotic organisms also include ribosome binding site sequences, and, in eucaryotes, termination signals. Additional factors necessary or helpful in effecting expression may subsequently be identified. As used herein, "control sequences" simply refers to whatever DNA sequence may be required to effect expression in the particular host used.

"Cells" or "recombinant host cells" or "host cells" are often used interchangably as will be clear from the context. These terms include the immediate subject cell, and, of course, the progeny thereof. It is understood that not all progeny are exactly identical to the parental cell, due to chance mutations or differences in environment. However, such altered progeny are included when the above terms are used.

B. Purification of PIP From Dialysis Fluid

In general, the purification of the hPIP of the invention was carried out as set forth in Figure 2. Alternative approaches are, of course, possible, but the procedure there set forth results in a homogeneous active preparation. The approach summarized with respect to the specific procedure as set forth in Figure 2 is, briefly, as follows:

Dialysis fluid sufficient to yield approximately 2 l of fluid is conveniently obtained in
one batch from patients undergoing continuous ambulatory peritoneal dialysis. Successive 2 l batches are processed as described below to obtain the desired quantity of pure product. The fluid is first subjected to increasing concentrations of ammonium sulfate: the fraction precipitated at approximately 40%-60% ammonium sulfate saturation contains the activity and is subjected to further purification. It is helpful to pre-precipitate proteins which are insoluble at less than 40% ammonium sulfate. The precipitates are recovered by centrifugation and then subjected to further purification.

In order to lower the salt concentration, the ammonium sulfate-containing fraction is dissolved in a suitable buffer of approximately pH 8 and then dialyzed against the same or comparable buffer at low temperature.

The dialyzed is then subjected to a treatment which removes the albumin component, the largest quantity contaminant. Chromatography on the affinity support Affi-gel blue previously equilibrated in the same buffer is suitable for this purpose. The desired PIP-containing fraction is not bound to the column under these conditions and appears in the flow-through volume, although contaminating proteins in the solution are retained by the column and are eluted at higher salt concentration.

The PIP fractions are treated with a lectin support, such as, for example, concanavalin-A sepharose, lentil lectin-sepharose, or peanut agglutinin-sepharose, preferably concanavalin-A sepharose equilibrated with similar pH 8 buffer. Again the desired activity does not adhere to the column under these conditions.

The PIP-containing flow through fractions are further purified by anion-exchange chromatography.
using, for example, DEAE cellulose, QAE-cellulose, or SP-cellulose, preferably DEAE cellulose, equilibrated in a similar buffer at approximately pH 8. The hPIP adsorbs to the column and fractions are eluted using a convenient salt gradient. The PA2 inhibitory activity of the eluate fractions is measured to ascertain the desired PIP fractions.

When the active fractions are subjected to preparative SDS-PAGE, SDS-PAGE yields an 18 kD band of inactive protein, and an active 40 kD band. The 40 kD band was eluted and reconstituted in the absence of detergent, to obtain protein exhibiting the desired activity. The preparative procedure is conducted substantially as described by Laemli, U.K., Nature (1970) 23:680-685; and an approximately 3 mm 12.5% gel is appropriate to purify a mixture containing 10 mg total protein.

The 40 kD band obtained as described has high PIP activity as demonstrated in a number of in vitro and in vivo assays as described in section D below, but contains, in addition to PIP, apoAIV and additional protein(s) of similar molecular weight. It is believed that apoAIV following PIP through this purification procedure confers stability on PIP, and that PIP may occur in situ as an apoAIV complex. Once isolated from apoAIV as described below, PIP becomes relatively labile. Therefore, it may be advisable to prepare PIP in pharmaceutical compositions in the form of this complex.

The association of PIP activity with a 40 kD protein was further confirmed by performing analytical RP-HPLC on the active fractions resulting from concanavalin-A sepharose treatment. The RP-HPLC resulted in a separation wherein the activity was
present in only one of a multitude of protein-containing eluted peaks. The active peak, when subjected to SDS-PAGE, yielded a single 40 kd band.

In addition, as further described below, the 40 kd band, when injected into rabbits, yielded polyclonal antisera capable of immunoreaction so as to bind PA2 inhibitory activity and so as to bind protein capable of forming a complex with phospholipase A. Therefore, although the immunogen also contains apoAIV, the elicited antibodies are reactive with PIP.

However, it is also possible to isolate human PIP free from associated proteins by subjecting the active eluate from anion exchange chromatography described above to isoelectric precipitation using sodium citrate buffer, pH 5.5, as shown in Figure 2. Dialyzing the active fractions against this buffer results in the precipitation of non-PIP contaminants, including apoAIV. The supernatant contains the human PIP, which is recovered as a pure 40 kd band by electrophoresis, as described above.

C. Utility and Administration

The PIP proteins of the invention show in vitro activity as phospholipase inhibitors, are capable of suppressing the production of PGE$_2$ in cell culture, and are effective in several in vivo models in combatting inflammation. Accordingly, the proteins of the invention are useful in ameliorating, treating, or reducing undesirable inflammatory symptomologies in human and veterinary subjects. The proteins of the invention are useful both to control inflammatory responses which are excessive, but formed in response to external stimuli such as infection or wounding, and to treat inflammatory disorders such as rheumatoid
arthritis, asthma, unwanted edema, dermatitis, arthritis, conjunctivitis, allergies, and lupus erythematosis.

Administration of the proteins of the invention is in a general dosage range of approximately 0.1-100 µg/kg, more preferably 0.1-10 µg/kg per host body weight. The quantity administered depends, of course, on the nature of the subject, the severity of the condition to be treated, and on the mode of administration. Intravenous injection, for example, generally requires smaller amounts than alternative routes. The PIP protein may be administered in a single dose, over several partial doses, or by constant infusion over a extended time period until the desired benefits are obtained.

The protein may be administered in aqueous solution or in the presence of additional pharmaceutical excipients, depending on the mode of administration desired. Protein pharmaceuticals are desirably administered by injection, such as subcutaneous, intravenous, or intramuscular injection, or parenterally through a membrane transfer. Aerosol or oral administration may also be possible in the presence of stabilizing compositions. Complexation with apoAIV is stabilizing to PIP in these compositions, as well as in forms intended for injection.

Injectables are prepared in conventional forms as liquid solutions or suspensions, in solid form suitable for reconstitution prior to injection, or as emulsions, either of PIP or of its apoAIV complex. Suitable excipients are, for example, water, saline, dextrose, and the like. Minor amounts of auxiliary substances such as buffering agents, emulsifying agents, and so forth may also be included.
Suppository administration may additionally employ binders and carriers such as polyalkylene glycols and triglycerides; aerosol administration, which would be especially suitable for relief of bronchial problems generally utilizes the PIP protein or its complex in finely divided form along with a surfactant and propellant. Typical surfactants include fatty acid esters; typical propellants are the lower alkanes or fluorinated alkanes, such as freon. Topical administration in the form of lotions or salves is also practical, and is preferred in the case of localized treatment.

Both the 40 kd SDS-PAGE eluate containing both PIP and apoAIV and the purified PIP protein of the invention are also useful in order to prepare antisera or monoclonal antibodies for immunoassays useful in diagnosis and in monitoring of therapy. Design of immunoassays is well understood in the art, and can take a variety of permutations. Either competitive antigen or antibodies can be labeled using radioactive materials, fluorescent materials, or enzymes. The assay may be conducted as a direct detection of the antigen-antibody complex, as a competition assay for immunocomplexing, or as a sandwich assay wherein the complex is further immunoreactive with an additional antibody. The assays may employ standard procedures; the contribution of the invention is the provision of suitable antigen, both for direct use as standards or competitive antigen for conduct of such assays and as antibody raising material for the preparation of suitable antisera.
D. Examples

The following describes an illustrative procedure for purification of hPIP. It is not to be construed as limiting, as additional variations may clearly be employed to result in an active, pure protein. However, the specific procedure presented does, in fact, result in a homogeneous (to SDS-PAGE) preparation of a 40 kd protein having hPIP activity, and in the preparation of human PIP free from associated proteins.

D.1. Purification of hPIP from Dialysis Fluid

Human PIP was isolated from dialysis fluid using a phospholipase (PA2) inhibition assay to monitor purification. Approximately 2 l of human peritoneal lavage fluid, obtained from a patient by continuous ambulatory peritoneal dialysis, was clarified by filtration through cheesecloth, and subjected to ammonium sulfate fractionation. Solid ammonium sulfate sufficient to obtain 40% saturation was provided, the resulting precipitate centrifuged at 10,000 x g for 20 min and the supernatant recovered. Sufficient solid ammonium sulfate was added to the supernate to provide 60% saturation, and the centrifugation process repeated. The precipitate, which contained the PA2 inhibition activity, was dissolved in 20 mM ammonium bicarbonate, pH 7.8 buffer (buffer A) containing 1 mM phenyl methyl sulfonyl fluoride (PMSF) and aprotinin at 50 µg/ml. The reconstituted solution was dialyzed against buffer A at 4°C to lower the total salt concentration, and shown to be active in the in vitro PA2 inhibition assay set forth below.

A portion of the dialyzate containing 50 mg of protein was applied to a 2.5 cm x 12 cm Affi-gel blue
(BioRad Laboratories, Richmond, California) column pre-equilibrated in buffer A. Two ml fractions were collected at a flow rate of 0.3 ml/min. The column was eluted with a NaCl salt gradient from 0-0.5 M NaCl. Fractions were assayed for PA2 inhibition activity, and all activity was shown to be in the flow through volume, as shown in Figure 3a. (In Figures 3a-3c the solid bars indicate PIP activity.)

The active fractions were pooled, lyophilized, and then reconstituted and applied to a 2.5 cm x 12 cm concanavalin-A sepharose column pre-equilibrated in buffer A. Elution at a flow rate of 0.2 ml/min yielded the elution profile shown in Figure 3b. Again, all activity, as assayed by the *in vitro* PA2 inhibition assay, was found in the flow through volume. The active fractions were pooled and lyophilized. A small portion of the active fraction pool was set aside for RP-HPLC analysis, as described below.

The lyophilized fractions were then reconstituted in buffer A and applied to a 2.5 cm x 12 cm column of DEAE-52 pre-equilibrated in buffer A and elution conducted using a 0-0.2 M linear NaCl gradient. Figure 3c shows the elution profile, and the presence of activity in fractions eluted at approximately 0.125 M NaCl.

The active DEAE eluate fractions were pooled, concentrated, desalted, and approximately 10 mg of the protein was loaded onto a 3 mm 12.5% polyacrylamide gel for electrophoresis separation according to the procedure of Laemli (supra) except that the disulfide bonds were not reduced with β-mercaptoethanol prior to fractionation. Protein bands were detected by a 3 min staining procedure using 0.1% Coomassie blue in 50% trichloroacetic acid, followed by 5 min of destain in 5%
acetic acid solution. Only two major protein bands resulted: one at 18 kD and the other at 40 kD. These bands were cut from the gel, minced into 9 mm³ cubes and the protein was eluted in buffer A overnight at 4°C. The eluate was treated to remove glycine, SDS and dye in several steps: first, the eluate was dialyzed against buffer A for 24 hr, and the dialyzate then concentrated by lyophilization. The lyophilized material was reconstituted in buffer A and extracted 3 times with 2 volumes of water saturated butanol. The aqueous layer including the interface was dried under nitrogen to remove remaining butanol and then allowed to stand at 4°C at 1 mg protein/ml for at least 24 hr to complete protein refolding. Upon assay in the PA2 inhibition in vitro assay, the 40 kD band was active, but the 18 kD band was not.

Figure 4 shows the comparative results of SDS-PAGE performed on the original extract, on the preparation at various stages of purification, and on the purified protein. The bands were developed using silver stain (BioRad Labs, Richmond, CA) by two successive oxidation and staining procedures according to the manufacturer’s instructions. Lane 1 contains molecular weight markers; lane 2 is the dialysis fluid before ammonium sulfate treatment; lane 3 is the 40%-60% ammonium sulfate precipitate; lane 4 contains the pooled active fractions from Affi-gel blue chromatography; lane 5 contains pooled active fractions from concanavalin-A sepharose chromatography; lane 6 contains pooled active fractions from DEAE chromatography; lanes 7 and 8 contain 1 µg and 50 ng respectively of the 40 kD band obtained from preparative gel electrophoresis. The entire procedure results in a purification of approximately 500 fold as shown by the results.
illustrated in Figure 5. Using a comparison of µg protein required for 50% inhibition, the specific activity of the crude extract is approximately 0.2% of that for the purified 40 kD band.

A portion of the active fractions resulting from concanavalin-A sepharose treatment described above was subjected to RP-HPLC using a C₈ column and elution with a gradient of acetonitrile in 0.1% trifluoroacetic acid. Figure 6 shows the elution profile for the column. A multiplicity of protein fractions are obtained, only one contains the activity. This active fraction was then subjected to analytical SDS-PAGE using a 12.5% gel, and the developed gels were stained with Coomassie blue G-250 or with silver reagent. Only a 40 kD band was observed in each case.

To obtain pure human PIP, the pooled active eluate from the anion exchange resin above was dialyzed against pH 5.5 sodium citrate buffer. Protein which precipitated was removed by centrifugation and the proteins in the supernatant were subjected to preparative SDS-PAGE. The 40 kD band is then recovered as described above. Alternatively the supernatant can be brought to pH 7.5 and passed through a column of PLA2-Sepharose as described by Parente, L., et al, Life Sci (1985) 36:1225-1231. After washing the column with 150 mM NaCl the bound hPIP is eluted with either 1.0 M NaCl or 0.1 M acetic acid in pure form.

D.2. Preparation of Anti-PIP Antibodies

The 40 kD band above was subsequently shown to be a mixture of proteins which includes hPIP and apolipoprotein AIV (apoAIV), as will be further described below. However, this mixture was capable of raising antibodies specifically reactive with hPIP. To
obtain anti-hPIP, New England white rabbits were injected subcutaneously or intramuscularly with 200 μg of the eluted 40 kd band fraction contained in complete Freunds adjuvant. The rabbits were boosted at 3-week intervals with the same vaccine. The rabbits were then bled from the ear vein 7-10 days after the boost, and the resulting serum was tested for its ability to bind the 40 kd eluate described above, using non-immune serum as control.

For the binding assay, 500 ng of purified hPIP-containing 40 kd protein was immobilized on individual wells of a polystyrene plate, and varying dilutions of antisera added to the wells. The quantity of specifically bound antibodies was quantified using 125I-labeled protein A (Amersham, Inc.). As shown in Table 1 below, a serum dilution of 1:400 shows a significant quantity of antibodies.

The immunoreactivity of the antisera was further used to show the progress of purification by Western blot. The samples to be tested against the antisera were diluted 1:1 with 2 x SDS:sample buffer (Laemli, supra) and 10–25 µg of protein is fractionated on 1.5 mm thick SDS-polyacrylamide gels (12.5% acrylamide). The fractionated proteins were electro-transferred to nitrocellulose sheets and immunoreactive 40 kd protein is detected with anti-hPIP antibody and \(^{125}\)I-Protein A, using a solution containing 5% BSA, 5% ovalbumin and 5% nonfat dry milk to block nonspecific sites. Controls were run in parallel against nonimmune rabbit serum.

Figure 7 shows the results of Western blot performed on the same fractions shown in Figure 4 obtained at various purification stages. Lane 1 is 43 kd \(^{125}\)I-ovalbumin, lane 2 is the dialysis fluid, lanes 3–5 are the active fractions from the Affi-gel Blue, Con-A sepharose and DEAE columns, respectively and lane 6 is the material obtained after preparative SDS-PAGE. The 40 kd band is specifically detected throughout purification.

The ability of the antisera to react specifically with hPIP, though raised in response to the 40 kd mixture, is shown by its ability to detect protein (PIP) specifically bound to phospholipase A2 (PA2), as
shown in Figure 8. PA2 (150 pmol) was immobilized on polystyrene wells and excess sites were blocked with human serum albumin. Increasing quantities of 40 kd protein were then added in the absence and presence of 1500 pmol free PA2 and binding continued for 30 min at 22°C. After washing, the bound PIP was detected using the anti-PIP antibody and ~I-protein-A. Wells containing HSA alone were also included as negative controls.

The results in Figure 8 show that antibodies bind increasingly to the wells when increasing amounts of the PIP-containing 40 kd mixture are added; however, this binding can be reduced to the nonspecific binding level of HSA-coated wells when 1500 pmol PA2 is preincubated with the PIP-containing 40 kd mixture. Thus, the antibodies bind to a protein which itself binds to PA2, a characteristic of PIP, but not of the other components of the 40 kd mixture.

Also, preincubation of the antiserum at 1:100 dilution with 10 µg of the 40 kd mixture neutralized its ability to detect protein bound to immobilized PA2.

D.3. Identification of mRNA Source for cDNA Production

The polyclonal antiserum raised against the purified 40 kd protein were used to screen various human cell-sources for the production of hPIP in order to identify a source for mRNA useful to obtain a cDNA library. In a convenient screening procedure solubilized cellular protein was assayed for hPIP immunoreactivity after fractionation on SDS-polyacrylamide gels.

Candidates for screening include cultured human inflammatory cells such as the monocyte-macrophage cell
lines U937 and HL60, and isolated human blood cells, such as polymorphonuclear cells (PMN), as well as lung tissue which is known to contain ~20% macrophages. The cells were incubated in appropriate culture media overnight, either containing serum or serum-free, in the presence and absence of dexamethasone (0.1 μM). Cell supernatants or the cells themselves, as appropriate, were assayed for protein immunoreactive with anti-hPIP.

For cell lysates, cells were washed free of any serum proteins and were lysed by the addition of phosphate buffered saline containing 5 mM MgCl₂, 0.1% NP-40, 0.1 mM PMSF, 50 μg/ml aprotinin at 4°C. Cells attached to culture plates were lysed directly on the dishes while suspension cells were collected by centrifugation and resuspended in the above buffer. After 3-5 min the lysate was collected from the culture dish and nuclei were removed by centrifugation (1000 x g, 5 min).

The samples (supernatants or lysates) to be tested against the antisera were diluted 1:1 with 2 X SDS:sample buffer (Laemmli, U.K., supra) and 50-100 μg of protein was fractionated on 1.5 mm thick SDS-polyacrylamide gels (12.5% acrylamide). The gels were developed as above with the addition of using anti-hPIP antisera preincubated with 50 μg of purified 40 kd protein as a control for nonspecific binding of the antibody. Following exposure of the nitrocellulose to x-ray film the hPIP immunoreactivity in several cell-types can be quantitated by densitometric scanning of the autoradiogram.

In certain cell-types hPIP is secreted into the culture media. Partially purified hPIP from such culture media are assayed as above. (In some cases, the conditioned media may be subjected to ammonium sulfate
fractionation and chromatography on Affi-gel blue and Con-A sepharose. Fractions which do not bind to the Con-A sepharose column are lyophilized and analyzed for hPIP immunoreactivity on Western gels as described.)

Figure 9 shows the results obtained from both serum-containing and serum-free media conditioned for 48 hours by U937 cells.

The PIP protein appears as a 37 kd band in the medium from serum-free cultured cells. The immunoreactive band at ~40,000 daltons is most probably apoAIV, as it is present in serum and in serum-containing U937-conditioned media, but not in serum-free U937-conditioned media. Likewise, the immunoreactive band seen at ~68,000 daltons represents albumin contained in the serum. The 50,000 dalton band is the IgG heavy chain, as it is only seen in serum-containing media and is also detected when nonimmune antiserum is used; the IgG heavy chain can bind 125I-protein A independent of the antibody used to probe the Western.

These results were confirmed by assaying the same samples derived from serum-free U937-conditioned media for PA2 inhibitory activity, as shown by inhibition of PGE₂ production in cultured mouse fibrosarcoma cells (see below). U937 cells were therefore selected to prepare a cDNA expression library for subsequent antibody screening.

D.4. Preparation of hPIP cDNA Construction of cDNA Libraries from Selected Cells
cDNA libraries were prepared initially from U937 cells, but PMN and lung cell preparations were also used.
Total cellular RNA was prepared from the selected cells by standard procedures (Chirgwin, J.M., et al., Biochemistry (1979) 18:5294-5299). Poly A⁺ RNA was isolated by two successive passes of the RNA over an oligo-dT cellulose column.

To provide the maximum likelihood of obtaining cDNA clones encoding hPIP, two separate cDNA libraries can be constructed, one using random primers (P. L. Biochemicals) and the other using an oligo-dT primer. In both cases, the first strand synthesis uses 15 µg of poly A⁺ RNA with the appropriate primer and is synthesized by reverse transcriptase (Avian Myeloblastosis Virus) using standard reaction conditions.

The second strand of each cDNA preparation is synthesized using RNase H (Gubler, U., et al., Gene (1983) 25:263-269) to hydrolyze the RNA from the DNA-RNA hybrid, followed by DNA polymerase (Klenow fragment) to fill-in the resulting single stranded regions, thus creating double stranded, blunt-ended cDNAs. Internal EcoRI restriction sites are protected by methylation using EcoRI methylase (New England Biolabs) according to the manufacturer's instructions, and synthetic oligonucleotide linkers containing an EcoRI site (P. L. Biochemicals) are then ligated to the blunt-ended cDNAs using T₄ ligase. Polymeric linkers are reduced to monomers by subsequent digestion with EcoRI, and the fragments can be screened to a specific size class by electrophoresis through low melting point agarose (1.5% agarose) and recovered, if desired.

The resulting double stranded cDNA is ligated into the unique EcoRI site of the bacteriophage, expression vector λgt11 as described by Young, R.A. and Davis, R.W., Science (1983) 222:778-782. Because the EcoRI site in this vector is in the correct reading
frame at amino acid position 1015 of the β galactosidase gene, any cDNA whose reading frame and orientation are also correct with respect to the EcoRI site may be expressed as a fusion protein with β-galactosidase upon induction with isopropyl thiogalactoside (IPTG). The random frequency of this occurring is one in six. (Two orientations times three reading frames.) The proteins expressed by such induced phage plaques were also screened with polyclonal antisera directed against hPIP prepared using the 40 kd protein above.

Following ligation of the cDNAs, the recombinant DNA was packaged in vitro using a commercial packaging extract (Amersham, Inc.) and the recombinant phage were titered on the host strain E. coli C600Hfl as described by Young, R.A., et al (supra). About 200,000 recombinants were obtained.

The cDNA library was screened by antibodies against hPIP. Appropriate titers of about $5 \times 10^5$ phage were incubated with E. coli Y1090, plated as described, and grown for 20 hr on ten 150-mm plates to yield the desired phage density (Young, R.A., et al, supra). Since the β-gal-fused PIP protein will be in the lysate, the top agar is overlayed with nitrocellulose and plates incubated overnight at 37°C. The nitrocellulose filters are then processed for antibody detection of the recombinant fusion proteins essentially as for Western blots, except that the antibody is preabsorbed with a lysate from bacteria infected with the phage vector (λgt11) alone.

In more detail, the filters were processed by first blocking nonspecific binding with 5% nonfat dry milk dissolved in PBS, 0.1% NP-40. The filters were incubated with a 1:100 dilution of the antiserum prepared above in PBS, 0.1% NP-40, 5% BSA, 5% ovalbumin,
for 2 hr and then washed in PBS, 0.1% NP-40. Bound antibody was detected using $^{125}$I-protein A (10$^5$ cpm/filter) and autoradiography of the washed filters.

Using this detection procedure positive clones were purified through successive rounds of screening until all plaques in each pool are positive. False positives were identified by performing a subsequent round of screening using duplicates at 100 plaques/2 cm$^2$ overlayed with 2 cm$^2$ nitrocellulose discs, and incubating the duplicate nitrocellulose discs with antibody which has or has not been pretreated with 10 μg of hPIP-containing 40 kd protein. Antibody binding to false positive clones should still occur with antisera pretreated with hPIP.

Phage DNA prepared from the five most intense positive clones was analyzed for size of the cDNA inserts and for sequence-relatedness.

All five cDNA inserts were approximately 200 bp. One of them, designated λU-200, was subcloned into the EcoRI site of pBR329 to give pU200, and into M13mp9 and M13mp8 for sequence analysis. Figure 10 shows the nucleotide sequence obtained and its deduced amino acid sequence. It was possible to deduce the correct reading frame from the length of the fusion proteins produced; these proteins were approximately 70 amino acids longer than the 8-gal. Therefore, following the linker the inserted sequences maintained a 200 bp open reading frame, presumably from an internal portion of the PIP protein. pU200 was therefore used to probe additional cDNA libraries.

Additional Libraries—PMN

Human white cells were prepared by sedimentation of blood through 6% dextran in 0.15 M
NaCl. The white cells in the supernatant were collected by centrifugation, washed in PBS and used for RNA isolation. A cDNA library in λgt10 was prepared as described above, except for using λgt10 as the cloning vector. This library was referred to as the PMN library. A λgt10 library was also prepared from the U937 cells, as above.

Each cDNA library was prepared for screening by growing approximately 10^6 phage on E. coli C600Hf1, and transferring plaque lysates to nitrocellulose filters. The filters were processed for hybridization as described by Benton, W.E., et al, Science (1977), 196:180-182. The probes were labeled by nick translation according to Maniatis, T., et al, Cloning Manual, and each filter was treated with 10^7 cpm pU200 in 1 ml of hybridization buffer at 42°C for 16 hr. The filters were then washed twice in 2 x SSC, 0.1% SDS at 22°C for 5 min, and then washed in 0.2 x SSC, 0.1% SDS at a more stringent temperature (60°C). The hybridized filters were then dried and positive signals detected by autoradiography.

The U937 λgt10 library yielded several hybridizing cDNAs, of which the longest was about 500 bp and designated λU500. The nucleotide sequence of λU500 was determined by dideoxy sequencing and is shown in Figure 11. Comparison of Figure 11 with Figure 10 shows that λU200 and λU500 share approximately 50 bp at the 5' ends of each and then diverge. This divergence was later shown to be due to intron splicing, as described below.

The λgt10 PMN library yielded four hybridizing positives having sizes of 400-600 bp; the longest cDNA was designated PMN600 and dideoxy sequenced. The sequence determined for PMN600, along
with the deduced amino acid sequence, is shown in Figure 12. PMN600 not only shares the 50 bp segment common to λU200 and λU500, but its homology with λU500 extends for another approximately 200 bp. These sequences then also diverge. This divergence was shown to be due to the presence of optional 3' terminal exons in the gene as set forth below.

**Human Lung cDNA Libraries**

cDNA libraries in λgt10 were prepared from human lung tissue using the procedure described above. Two such libraries were obtained, one from fetal lung tissue and the other from adult lung. Lung tissue contains approximately 20% macrophage by weight, and the production of PAz inhibitors from guinea pig lungs has been reported. (Flower, R.J., et al, *Nature* (1979) 278:456-459.)

The fetal lung library was probed as described above using a synthetic oligonucleotide of the sequence 5'-GAAGGTAGCCACAGCCACGG-3', which represents the bases 23-42 of the sequence of PMN600 (Figure 12). A positively hybridizing cDNA contained additional upstream sequences which could, in fact, be mapped onto an upstream exon of the genomic clone described below. This cDNA was subcloned into pBR329, designated pSR-1 and used as follows to determine the size of the PIP encoding mRNA:

When human lung poly-A⁺ RNA was subjected to Northern blot, using pSR-1, as probe, the mature mRNA was shown to be approximately 1400 bases in length. Primer extension analysis, using a 586 bp BamHI fragment from pSR-1 as the primer, showed that an additional 500 bases were required to obtain full-length cDNA.
A Full Length hPIP cDNA

The adult human lung cDNA library was therefore screened using two probes: PMN600 cloned into pBR329 (p600), and a synthetic oligonucleotide 5'-ATGAGCTGTGAGACGGGCGG-3', which maps to the 5' end of pSR-1. Four positively hybridizing plaques were purified and sized, and found to contain either 1360 or 1340 bp. These cDNAs were cloned into M13mp8 and M13mp9 for dideoxy sequencing, and one of them shown to contain the full-length coding sequence for hPIP. Figure 13 shows the complete DNA sequence and the deduced amino acid sequence encoded by this clone, pLE-1 which corresponds to a primary translation product of 331 amino acids representing a protein of approximately 36.5 kd. The mature protein is believed to begin at nucleotide 112-114, encoding leucine.

An in vitro translation product of pLE-1 was obtained by subcloning the pLE-1 insert into the transcription vector SP-6 with the addition of RNA polymerase (SP6 System, Amersham Corporation, Arlington Heights, IL) according to the manufacturer's instructions, and then subsequently translating the mRNA produced in a reticulocyte lysate system (Bethesda Research Laboratories, Bethesda, MD) in vitro. The translation product showed the predicted size of 36 kd. It is believed that the discrepancy between the 36 kd protein encoded and the 40 kd protein associated with peritoneal fluid is due to glycosylation. The sequence of pLE-1 has four canonical glycosylation sites (Asn-X-Ser/Thr) beginning at bases 625, 595, 709, and 808. This was confirmed by injecting RNA transcribed as above from SP6-pLE-1 into Xenopus laevis oocytes (which can glycosylate the primary translation product) and localizing the mature 40 kd product in the membrane fraction of the oocytes.
D.5. **Isolation of Genomic Clones Encoding hPIP**

The complete DNA sequence encoding hPIP was also isolated from a human genomic library. The pU200 and the NcoI fragment containing bases 198-590 from p600 were used as probes; they have no common sequences. The library, in λ Charon phage, was constructed from Sau3AI-digested human DNA by the method of Maniatis, T. (supra) pp 270. For screening, $10^6$ phage are grown and plaque lifts are performed as above using triplicate nitrocellulose filters. The filters are hybridized using the above probes, and the filters are washed under stringent conditions in 0.2 x SSC, 0.1% SDS, 60°C. Plaques which are positive in duplicate are picked, eluted, and replated for second round screening. The procedure is repeated until the phage are plaque-purified.

Two plaque-purified phage recombinants hybridizing to pU200 probe and 7 positives hybridizing to the NcoI fragment were obtained. Purified DNA from each of these clones was restricted using EcoRI and the resulting fragments blotted to nitrocellulose for probing with pU200 or the NcoI fragment. One of the recombinant phages, λl2-3, yielded fragments which were positive with both probes; λl2-3 contained exons II, III, IV and V and lacked only exon I. Additional restriction enzyme mapping showed that λl2-3 overlapped the other clones. Exon I is contained in λCM-14, a genomic clone which did not hybridize to the NcoI fragment but did hybridize to pU200. Restriction analysis and sequencing of the λl2-3 clone and further analysis of the other positive clones showed that exon V appears to be provided in an alternate form VA, as shown in Figure 14. Exon VA, is not present in λl2-3, but
is found in λ12-1, a genomic clone which hybridizes to the NcoI fragment and pU500.

Comparison of the sequences in the gene and in the cDNA clones obtained shows that the divergence of pU200 from the other clones after 50 bp is due to failure to splice out an intron, and that the divergence between PMN600 and λU500 downstream of their 250 bp homologies is due to the alternative V and VA exon availabilities. λU500 contains exon VA; PMN600 contains exon V, as does pLE-1.

D.5. Construction of Expression Vectors and Expression of hPIP

Mammalian Vectors

The cDNA clone encoding hPIP is conveniently used to produce the recombinant protein in a variety of hosts, as set forth in W.E.1 below. However, expression in mammalian systems is favored as the host is capable of post translational processing analogous to that experienced by the natively produced protein. Either cDNA or genomic sequences may be used, as the host is also capable of processing introns.

The full length cDNA hPIP encoding clone, pLE-1 is inserted as an EcoRI fragment into the mammalian expression vector pHS1 as described below.

Construction of pHS1, the Host Expression Vector

The plasmid pHS1 contains 840 bp of the hMT-II sequence from p84H (Karin, M., et al. Nature (1982) 299: 297-802) which spans from the HindIII site at position -765 of the hMT-II gene to the BamHI cleavage site at base + 70. Plasmid p84H was digested to completion with BamHI, treated with exonuclease Bal-31 to remove
terminal nucleotides, and then digested with HindIII. The desired 840 bp fragment was ligated into pUC8 (Vieira, J., et al, Gene (1982) 19: 259-268) which had been opened with HindIII and HincII digestion. The ligation mixture was transformed into E. coli HB101 to Amp\(^R\), and one candidate plasmid, designated pHS1, was isolated and sequenced by dideoxy sequencing. pHS1 contains the hMT-II control sequences upstream of a polylinker containing convenient restriction sites.

Construction of hPIP Expression Vectors

The EcoRI hPIP encoding fragment, prepared as above, was ligated into EcoRI-digested pHS1 and the ligation mixture transformed into E. coli MC1061 to Amp\(^R\). Successful transformants were screened by restriction analysis, and a strain containing the desired plasmid, pMT-PIP is further propagated to prepare quantities of plasmid DNA.

Additional expression vectors containing modified coding sequences for the hPIP protein were also prepared from modified coding sequences designated pLE-2 and pLE-3. pLE-2 lacks the sequence at the C-terminal region of the hPIP protein, which is believed to be responsible for its binding to the cellular membrane. pLE-2 was constructed by subjecting M13 phage harboring the pLE-1 sequence shown in Figure 13 to site-directed mutagenesis to place a TAA stop codon at base 951 to replace TAC (encoding a tyrosine residue). The oligonucleotide 5'-'-CACTGCAGTACTGGG-3' was used as a primer and the mutated sequences were retrieved by screening the recombinant phage plaques using kinased oligonucleotide 5'-GCAGCCCCACTGCAGTACTGGACATCCAG-3' as a probe, under stringent washing of 55°C, 3 M tetramethyl ammonium chloride.
The mutagenesis was confirmed by dideoxy sequencing and the single-stranded form converted to double-stranded DNA. Correct functioning of the stop codon was also confirmed by subcloning the EcoRI insert into the SP6 vector system, transcription with RNA polymerase, followed by translation in the reticulocyte lysate system. SDS-PAGE of the isolation product shows a 34 kd protein, as compared to the 36.4 kd protein obtained from full-length hPIP-encoding sequences. The SP6 mRNA was also injected into Xenopus oocytes. Media conditioned by the injected cells for 18 hr showed PIP activity as assayed by the release of labeled arachidonate from zymosan-stimulated mouse peritoneal macrophages. Media conditioned by oocytes injected with mRNA from the LE-1 sequences cloned into SP6 failed to show activity in this assay. The EcoRI insert was transferred into pHS-1, as described above for the construction of pLE-1 to give pMT-PIP(-). The ligation mixture was transformed into E. coli HB101 to AmpR and the correct orientation and placement confirmed by restriction analysis.

pLE-3 contains an alternate 3'-terminal sequence encoded by the VA exon which had been retrieved in pU500 above. pLE-3 was constructed by replacing the downstream sequences in pLE-1 with the appropriate fragment from pU500: pLE-1 was digested with NcoI and EcoRI and the unique 718 bp fragment purified. pU500 was digested with EcoRI and NcoI and the unique 419 bp downstream portion of the cDNA insert purified. Ligation of these fragments resulted in a 1137 bp fragment which was inserted into the EcoRI site of pUC8 and transfected into E. coli HB101 cells for amplification and plasmid purification. Plasmids
containing the correct orientation and placement of the insert were designated pLE-3.

pLE-3 coding sequences were modified by addition of a polyadenylation signal to the 3' untranslated sequence by digesting pLE-3 with AvrII, blunting, and further digesting with EcoRI to obtain the hPIP encoding fragment. The unique 1037 bp cDNA insert was then isolated. A poly-A addition site derived from apoAI cDNA was isolated by digesting plasmid pBL13Al (Seilhamer, J., et al. DNA (1984) 3:309-317) with NarI, blunting, further digesting with EcoRI, and purifying the unique 65 bp fragment containing the entire apoAI 3' untranslated region. This 65 bp fragment was ligated to the hPIP cDNA, mixed with EcoRI-digested pHSI and further ligated to yield pMT-PIP/A. The ligation mixture was then transformed into E. coli MC1061 to Amp R. Plasmids from Amp resistant colonies were screened for the correct size insert.

For efficient secretion of the expressed hPIP it may be advantageous to employ an alternative signal sequence, such as that derived from human growth hormone, human alolipoprotein AI, human lung surfactant, or human renin. This can be accomplished using standard procedures i.e., by digesting pLE-1, pLE-2 or pLE-3 with SphI to remove the 5' end of the cDNA, replacing lost codons of the mature protein, and ligating the appropriate signal sequences upstream therefrom. Because the first amino acid of mature hPIP is predicted to be the leucine beginning at base 112 of Figure 13 and SphI cuts at base 124 it is necessary to reconstruct the first four amino acids using oligonucleotides encoding Leu-Arg-Cys-Met.
Production of hPIP by Mammalian Recombinants

Chinese hamster ovary (CHO)-K1 cells were grown on medium composed of a 1:1 mixture of F12 medium and DME medium with 12% fetal calf serum. The competent cells are co-transformed with pMT-PIP, pMT-PIP(-), pMT-PIP/ or pAc-PIP/A and pSV2:NEO (Southern, P., et al., J Mol Appl Genet (1982) 1: 327-341). pSV2:NEO contains a functional gene conferring resistance to the neomycin analog G418. In the transformation, 500 ng of pSV2-NEO and 5 µg of pMT-hPIP are applied to a 16 mm dish of cells in a calcium phosphate-DNA co-precipitate according to the protocol of Wigler, M., et al., Cell (1979) 16: 777-785. with the inclusion of a two minute "shock" with 15% glycerol after four hours of exposure to the DNA. A day later, the cells are subjected to 1 mg/ml G418 to provide a pool of G418-resistant colonies.

Successful transformants, also having a stable inheritance of PIP-encoding plasmid were plated at low density for purification of clonal isolates. For transformants containing PIP sequences under control of the MT promoter, small amounts of these isolates were grown in multi-well plates and induced with 10^{-4} M zinc chloride for convenient assay. hPIP production was assayed by demonstration of inhibition of induced PA2 activity in the cultured cells.

Seventy-two hr after transfection with either pSV2:NEO or pSV2:NEO/pMT-PIPL, the cells were labeled with C-14 arachidonic acid for 2 hr. The cells were washed, stimulated with either 10% fetal calf serum or 10 μM A_{23187}, a calcium ionophore, both standard activators of cellular PA2, and the release of labeled arachidonic acid from the cellular membranes was measured. Cells transformed with the pSV2:NEO alone showed 30-90% more release of arachidonic acid after 20
min than those co-transfected with the pMT-PIP (see Figure 14). Clonal isolates which produce large amounts of the desired hPIP as shown by PA2 inhibition are picked for direct assay.

For direct assay of PIP production, these cells were seeded at 1/10 confluency in basal medium supplemented with 10% fetal calf serum and grown to confluence in 850 cm² roller bottles. The cells were then washed and induced for hPIP production over 24 hr by addition of zinc chloride $10^{-4}$ M and dexamethasone $10^{-6}$ in serum-free medium.

Both media and cell membrane were assayed for PIP activity. The media were harvested and concentrated by Amicon UM-100 ultrafiltration. To obtain the membrane, the cells were treated with 1 mM EDTA and collected by centrifugation at 100 x g for 5 min. The cell pellet was resuspended in 2 ml of 10 mM Tris, pH 8, 250 mM sucrose, 150 mM NaCl, 1 mM EDTA, 1 mM PMSF, and broken in a glass homogenizer, monitoring the cell rupture by phase contrast microscopy. The nuclei were removed by centrifugation for 5 min at 1000 x g, and the supernatant lysate was fractionated into soluble and membrane fractions by centrifugation at 100,000 x g for 1 hr. The nuclear fraction was extracted with 0.1% Tween-20, and insoluble material removed by centrifugation. The membrane pellet from the lysate supernate was resuspended in homogenizing buffer, which further included 10% glycerol.

The media, cell lysate soluble fraction, membrane, and nuclear extract fractions were then assayed for PIP activity using two separate assays: Inhibition of the release of labeled arachidonic acid from the cellular membranes of zymosan-stimulated mouse resident peritoneal macrophages as described by Bonney,

P., et al. *Life Sci* (1985) 36:579-583. Only the membrane fraction shows activity in both of these assays. The other fractions obtained showed no activity. These results are shown in Figure 15. In the *E. coli* assay, membrane from pMT-PIP-transformed cells reduced hydrolysis of *E. coli* membranes from approximately the 50% shown by the controls to approximately 30%. In the zymosan-mediated macrophage assay release was only 80% of control.

Similar results in these assays were obtained from pMT-PIP(-) transformed CHO cells, except that activity was found in the media rather than in the membrane-bound fractions.

If desired, the hPIP secreted into the medium can be purified according to the procedures set forth above for the native protein, or by other standard methods known in the art.

**Bacterial Vectors and Expression**

**Construction of pTRP-233 Bacterial Expression Plasmid**

The ten oligodeoxynucleotides shown below:

```
5' AGAATTCATATGACGACTTTAGAGCTGAGATGTTCTAGACGTCAAGAAGGGATCCCACTAAGCTGAGATGTTCTAGACGTCAAGAAGGGATCC
3' TCTAGACGTCAAGAAGGGATCCCACTAAGCTGAGATGTTCTAGACGTCAAGAAGGGATCC

5' CTAGAAGGGATCCCACTAAGCTGAGATGTTCTAGACGTCAAGAAGGGATCC
3' GGATCCCACTAAGCTGAGATGTTCTAGACGTCAAGAAGGGATCC
```

```
were used to construct a synthetic trp promoter/operator. Five hundred pmole of each oligodeoxynucleotide except 1 and 10 were individually kinased using $^{32}$P-$\gamma$ATP. Pairs of these oligos, e.g. 1+2, 3+4, 5+6, etc, were annealed by incubating of 16.7 pmol each at 90°C for 2 min followed by slow cooling to room temperature, and were recovered following phenol/chloroform extraction and ethanol precipitation. The sets of pairs were ligated together with T4 ligase and the ligated DNA recovered and digested with EcoRI and PstI. The resulting DNA fragments were visualized by wet gel autoradiography and a 100 bp fragment was eluted and dideoxy sequenced to confirm the designed double stranded sequence above which contains promoter and operator regions of the trp operon and the ribosome binding site of the trp leader peptide.

Plasmid pKK233-2 (Amann, E., et al. Gene (1985) 40:183-190) was digested to completion with NdeI blunted, and religated to obtain the corresponding plasmid lacking the NdeI site, pKK-233-2-Nde.

Ten ng pKK-233-2-Nde was digested to completion with EcoRI and PstI, treated with CIP, and mixed with 50 ng of the synthetic EcoRI/PstI trp promoter/operator sequence described above. The mixture was ligated with T4 DNA-ligase, followed by transformation into E. coli JA221 lpp-'/lacI'. Transformants were screened for the presence of plasmid DNA containing the desired insert; designated pTRP-233.

**Bacterial Expression Vectors for PIP**

The hPIP encoding segments lacking the native signal sequence were removed from pLE-1, pLE-2, and pLE-3 by digestion with SphI, which cuts at nucleotide 114, as shown in Figure 13, blunting with Klenow, and
then digestion with HindIII which cuts at a vector site just 3' of the insert. The SphI(blunt)/HindIII fragments were ligated into the KpnI(blunt)/HindIII digested pTRP233, placing the coding sequences under control of the trp promoter, to give pTRP-PIP, pTRP-PIP(-), and pTRP-PIP/A, respectively. The ligation mixtures were transformed into E. coli HB101 to verify correct orientation, and these transformants were grown under standard M9 salts plus 0.5% casamino acids (Difco) to OD-550 of 0.1 before induction with 25 µg/ml IAA with further growth to OD 1.0. The bacteria were then harvested, lysed with a French press or by sonication, and the lysate assayed for PA2 inhibition using the in vitro assay of Vadas et al (supra).

The hPIP protein is obtained in nonglycosylated form and can be purified using standard procedures, following the purification by the PA2 inhibition assay. A fraction precipitating at 40-60% saturated ammonium sulfate is resolubilized in 25 mM Tris-HCl, pH 8.0, 2 mM EDTA, and subjected to DEAE Sephadex equilibrated with the same buffer. The protein is eluted in a NaCl gradient at 0.125 M, and purified to homogeneity on a C8 HPLC column or other hydrophobic column, from which active fractions elute at about 50% acetonitrile on a 20-100% acetonitrile gradient in 1% TFA. The dried protein in the active fractions is resolubilized in 20 mM Tris, pH 8.0, and reoxidized, if necessary, to the disulfide according to the method of Van Scherpenberg, G.M., et al, Hoppe-Seyler's Z Physiol Chem (1980) 361:571-576.

D.6. Active Fragments of hPIP

Figure 17 shows a comparison of the amino acid sequences of the hPIP of Figure 13 between nucleotide
positions 490-852 with the known sequences of pancreatic
and C. atrox venom phospholipases. This region of
homology is suggested as sufficient for activity, by
analogy with the Vipera system, which also shows
homology between enzyme and inhibitor (Mancheva, I., et
This region of hPIP with various downstream sequences is
obtained as a BstEII(blunt)/HindIII fragment from pLE-1,
pLE-2, and pLE-3. (BstEII cuts at base 465.) The
fragment is ligated into KpnI(blunt)/HindIII digested
pTRP233, as above, to obtain pTRP-PIP(F), pTRP-PIP(F-),
and pTRP-PIP(F/A) respectively. These plasmids were
expressed in E coli as above described.

In addition, any of the above vectors can be
modified to encode only the desired fragment
representing the desired homologous region. This is
accomplished by coverting the CAA glutamine codon at
nucleotide positions 853-855 to a TAA stop codon by site
specific mutagenesis.

pTRP-PIP(F) is digested with HindIII and EcoRI
and cloned into HindIII/EcoRI digested M13mp18. The
single stranded DNA is treated with DNA polymerase using
5'-GCATGTTAGCACATT-3' as primer, and the resulting
double stranded DNA transfected into competent cells.
The mutagenized phage are probed with
5'-AGGTGGGCATGTTAGCACATTGAGG-3' under stringent
conditions, and the purified plaques sequenced to
confirm correct construction. The recovered DNA is
reconstituted into double stranded form, digested with
EcoRI and HindIII, and ligated into EcoRI/HindIII
linearized pTRP-PIP(F). The resulting vector,
designated pTRP-PIP(465-852) is transformed into E coli
for expression. The active PIP fragment produced is
then purified and reduced/oxidized as described above.
D.7. ApoAIV Sequences and hPIP Sequences

The protein obtained in ¶D.1 as a 40 kd band on SDS-PAGE contained hPIP in N-terminal blocked form and apoAIV with an N-terminus available for sequencing. When the entire fraction was subjected to sequencing using Applied Biosystems 470A gas phase sequencer, the presence of the apoAIV N-terminus was confirmed. Approximately 50 μg of the protein were subjected to N-terminal sequencing, and PTH amino acids were identified with a Beckman 334T HPLC using an IBM CN column as described by Hunkapiller, M.W. and Hood, L.E., Meth Enzym (1983) 91:486-492. The N-terminal sequence obtained was:

Glu-Val-Ser-Ala-Asp-Gln-Val-Ala-Thr-Val-Met-Trp-
Asp-Tyr-Phe-Ser-Gln-Leu-Ser-Asn-Asn-Ala-Lys-Glu-Ala-Val-
Gln-Leu-Lys-Ser-Arg.

A minor secondary sequence of the 40 kd mixture could also be read. The sequence obtained was:

Glu-Asn-Leu-Pro-Gln-Asn-Gly.

Presumably the sequence arises from an internal proteolytic clip of the blocked hPIP molecule, which contains extensive disulfide bonding. This sequence begins at base 662 of the sequence shown in Figure 13 and ends at base 693.

D.8. Activity Content of the 40 kd Band Assay for Phospholipase A2 Inhibition

The standard in vitro inhibition assay (PA2 inhibition assay) was performed as follows:

100 ng of porcine pancreatic phospholipase AII (Sigma Chemical Co, St. Louis, MO) and various concentrations of the protein to be tested (up to 10 μg) were placed in 50 μl of buffer containing 20 mM Tris, pH 8.0 and 2 mM calcium ion. The solutions were
incubated at 30°C for 10 min, and then 100 µl of a solution containing 20 µg human serum albumin and 2 µCi of α-β-[14C]-arachidonyl phosphatidylcholine stearoyl (3H) (Amersham, Inc.) in the foregoing buffer (which solution had been sonicated 2 min in a sonication water bath at 22°C immediately prior to addition) was added. After 15 min at 30°C, the reaction was stopped by adding 25 µl of 10 N acetic acid.

Portions 25-50 µl of the reaction mixture were applied to silica G type TLC plates for analysis in an ascending solvent system containing chloroform, methanol, acetic acid (90:10:1). Arachidonic acid was used as a standard to locate the arachidonic acid band; the phosphatidyl choline band remains at the origin. The spots were visualized by staining with iodine vapor, and the labeled arachidonate and phosphatidyl choline spots were scraped from the plate and radioactivity determined using scintillation counting in toluene-omnifluor (New England Nuclear). The percent hydrolysis was computed as a fraction 100 x cpm arachidonic/(cpm arachidonic + cpm phosphatidyl choline).

Assay by PGE2 Production Inhibition

The hPIP was also shown to be capable of inhibiting the production of PGE2 by cultured fibrosarcoma cells. In this assay, confluent cultures of mouse fibrosarcoma cells obtained from ATCC (ATCC #CCL148) were preincubated with various concentrations of the protein to be assayed and 25 µl phosphate buffered saline in 150 µl HAMMs F10 medium (Gibco) for 15 min at 37°C. One hundred µl of F10 medium containing 2% fetal calf serum was added, and the cells were incubated for an additional hour at 37°C in a humidified incubator with a 5% CO2/95% air
atmosphere. Controls used dexamethasone (DEX) added to the cells 16 hr prior to induction. The media were removed and assayed for PGE$_2$ using a commercial radioimmunoassay kit (Seragen, Inc., Boston, MA).

Figure 18 shows the inhibition of PGE$_2$ production by purified (by SDS-PAGE) PIP and by DEX. The 18 kD band from the gel (open circles) was used as a control. The closed circles are the results using active fractions from the Con-A Sepharose column. The squares are the results with protein from the 40 kD band; the triangles are results using DEX. The response is dose-dependent for the active proteins and for DEX. The addition of 100 µg of arachidonic acid to the cells (added at the same time PIP was applied) was able to override inhibition by both PIP and DEX.

In Vivo Assays

Three in vivo models were employed to demonstrate the activity of PIP: the rat pleurisy model, the rat paw edema model, and the adjuvant-induced arthritis model.

In the rat pleurisy model, the pleural cavities of three groups of rats were inflamed by the injection of 0.1 ml of 0.5% carrageenin in saline, and the ability of the test substances to control the inflammation was measured. For detection of the activity of the PIP protein, 10 µg of PIP were injected along with the carrageenin. Carrageenin injections containing 200 µg of DEX were used as positive controls. Five hours later the pleural cavity was opened, washed with 1 ml saline, the fluid volume recorded; and the protein concentration in the fluid was determined by the method of Bradford, et al, Anal Biochem (1976) 72:248-254. Inhibitory activity was shown by decrease in the exudate volume and
exudate protein. Ten $\mu$g of the purified PIP was as effective as 200 $\mu$g DEX in suppressing both of these parameters, as shown in Figure 19.

The data on the left record the quantity of protein exuded in mg/cavity. The quantity is reduced essentially to normal levels in the presence either of 50 $\mu$g DEX or 10 $\mu$g PIP. The measure of exudate volume is shown on the right in ml. Again either 50 $\mu$g DEX or 10 $\mu$g PIP reduce the exuded fluid volume to normal levels.

In the rat hind paw edema model, groups of male Sprague-Dawley rats (180-200 g) were lightly anesthetized under ether and hind limb edema was induced by injection of 0.1 ml of a 0.5% weight/volume carrageenin suspension into the plantar tissue of the right hind paw (Van Arnie, C., et al, J Pharm Exp Therap (1965) 150:328-334.

The anti-inflammatory activity of test substances was examined by administering the test substance in one of three ways: either intravenous injection, intraperitoneal injection, or co-injection with the carrageenin. Except when specified, dexamethasone administered intraperitoneally 3 hr previously, was used as a control. Results were evaluated by measuring the thickness of the hind paw with a constant-pressure caliper starting at time zero (the time of injection of the test substance), and every 60 minutes thereafter.

Figure 20 shows the results as increase in foot pad thickness ($\text{mm} \times 10^2$) of determinations using 0-5 $\mu$g of the purified hPIP, isolated from SDS-PAGE, in experimental injections or 2.5 $\mu$g dexamethasone in control injections, each co-administered with the carrageenin. The hPIP significantly reduced the edema.
in a dose-dependent manner. The control DEX also reduced the inflammation, although the time dependence, as shown in Figure 20, is slightly different from that of PIP.

Figure 21 shows the results when injection of the test materials was made intraperitoneally 30 min prior to inducing inflammation. Indomethacin as well as DEX was used as a control. The data show that PIP and indomethacin are comparably effective in suppressing paw swelling, although both were slightly less effective than DEX. Accordingly, hPIP is able to enter the circulation and act at the site of inflammation.

Figure 22 shows the results when administration was made by injection into the femoral vein 2 min prior to the injection of carrageenan. Again, hPIP was effective in inhibiting inflammation over 3, 4, or 5 hr following IV administration in a dose-dependent manner, and 25 µg of PIP were equivalent to the effect of 200 µg DEX after 3 or 4 hr. The results permitted an estimate of the biological half-life of 2–3 hr for PIP.

The remaining in vivo assay was the adjuvant-induced arthritis model, according to the method of Colpaert, F.C., et al, Life Sci (1982) 31:67-75. Thirty days following induction, the animals received intramuscular injections of saline, purified hPIP, or dexamethasone. hPIP, as shown in Figure 23, was successful in producing a rapid diminution of hind paw and joint swelling which reached a maximum by 10 hr but the swelling returned to control levels after 28 hr. DEX produced swelling reduction after 3 hr, which was maintained for the full 28 hr experimental period.
E. Standard Methods

Most of the techniques which are used to transform cells, construct vectors, extract messenger RNA, prepare cDNA libraries, and the like are widely practiced in the art, and most practitioners are familiar with the standard resource materials which describe specific conditions and procedures. However, for convenience, the following paragraphs may serve as a guideline.

E.1. Hosts and Control Sequences

Both procaryotic and eucaryotic systems may be used to express the PIP encoding sequences; procaryotic hosts are, of course, the most convenient for cloning procedures. Procaryotes most frequently are represented by various strains of E. coli; however, other microbial strains may also be used. Plasmid vectors which contain replication sites and control sequences derived from a species compatible with the host are used; for example, E. coli is typically transformed using derivatives of pBR322, a plasmid derived from an E. coli species by Bolivar, et al. Gene (1977) 2:95. pBR322 contains genes for ampicillin and tetracycline resistance, and thus provides additional markers which can be either retained or destroyed in constructing the desired vector.

Commonly used procaryotic control sequences which are defined herein to include promoters for transcription initiation, optionally with an operator, along with ribosome binding site sequences, include such commonly used promoters as the beta-lactamase (penicillinase) and lactose (lac) promoter systems (Chang, et al, Nature (1977) 198:1056 and the tryptophan (trp) promoter system (Goeddel, et al Nucleic Acids Res (1980) 8:4057 and the
lambda derived P

In addition to bacteria, eucaryotic microbes, such as yeast, may also be used as hosts. Laboratory strains of Saccharomyces cerevisiae, Baker's yeast, are most used although a number of other strains are commonly available. Vectors employing, for example, the 2 μ origin of replication of Broach, J. R., Meth Enz (1983) 101:307, or other yeast compatible origins of replications (see, for example, Stinchcomb, et al., Nature (1979) 282:39, Tschempe, et al., Gene (1980) 10:157 and Clarke, L. et al., Meth Enz (1983) 101:300) may be used. Control sequences for yeast vectors include promoters for the synthesis of glycolytic enzymes (Hess, et al., J Adv Enzyme Reg (1968) 7:149; Holland, et al., Biochemistry (1978) 17:4900).

Additional promoters known in the art include the promoter for 3-phosphoglycerate kinase (Hitzeman, et al., J Biol Chem (1980) 255:2073), and those for other glycolytic enzymes. Other promoters, which have the additional advantage of transcription controlled by growth conditions are the promoter regions for alcohol dehydrogenase 2, isocytochrome C, acid phosphatase, degradative enzymes associated with nitrogen metabolism, and enzymes responsible for maltose and galactose utilization. It is also believed terminator sequences are desirable at the 3' end of the coding sequences. Such terminators are found in the 3' untranslated region following the coding sequences in yeast-derived genes.

It is also, of course, possible to express genes encoding polypeptides in eucaryotic host cell cultures derived from multicellular organisms. See, for example, Axel, et al, U.S. patent 4,399,216. These systems have the additional advantage of the ability to
splice out introns and thus can be used directly to express genomic fragments. Useful host cell lines include VERO and HeLa cells, and Chinese hamster ovary (CHO) cells. Expression vectors for such cells ordinarily include promoters and control sequences compatible with mammalian cells such as, for example, the commonly used early and late promoters from Simian Virus 40 (SV 40) (Fiers, et al., *Nature* (1978) 273:113), or other viral promoters such as those derived from polyoma, Adenovirus 2, bovine papilloma virus, or avian sarcoma viruses. The controllable promoter, hMT-II (Karin, M., et al, *Nature* (1982) 299:797-802) may also be used. General aspects of mammalian cell host system transformations have been described by Axel (supra). It now appears, also that "enhancer" regions are important in optimizing expression; these are, generally, sequences found upstream or downstream of the promoter region in non-coding DNA regions. Origins of replication may be obtained, if needed, from viral sources. However, integration into the chromosome is a common mechanism for DNA replication in eucaryotes.

**E.2. Transformations**

Depending on the host cell used, transformation is done using standard techniques appropriate to such cells. The calcium treatment employing calcium chloride, as described by Cohen, S.N., *Proc Natl Acad Sci (USA)* (1972) 69:2110, or the RbCl₂ method described in Maniatis, T., et al, *Molecular Cloning: A Laboratory Manual* (1982) Cold Spring Harbor Press, p. 254 may be used for procaryotes or other cells which contain substantial cell wall barriers. For mammalian cells without such cell walls, the calcium phosphate precipitation method of Graham and van der Eb, *Virology*

E.3. **Vector Construction**

Construction of suitable vectors containing the desired coding and control sequences employs standard ligation and restriction techniques which are well understood in the art. Isolated plasmids, DNA sequences, or synthesized oligonucleotides are cleaved, tailored, and religated in the form desired.

Site specific DNA cleavage is performed by treating with the suitable restriction enzyme (or enzymes) under conditions which are generally understood in the art, and the particulars of which are specified by the manufacturer of these commercially available restriction enzymes. See, e.g., New England Biolabs, Product Catalog. In general, about 1 μg of plasmid or DNA sequence is cleaved by one unit of enzyme in about 20 μl of buffer solution; in the examples herein, typically, an excess of restriction enzyme is used to insure complete digestion of the DNA substrate.

Incubation times of about one hour to two hours at about 37°C are workable, although variations can be tolerated. After each incubation, protein is removed by extraction with phenol/chloroform, and may be followed by ether extraction, and the nucleic acid recovered from aqueous fractions by precipitation with ethanol. If desired, size separation of the cleaved fragments may be performed by polyacrylamide gel or agarose gel electrophoresis using standard techniques. A general

Restriction cleaved fragments may be blunted ended by treating with the large fragment of E. coli DNA polymerase I (Klenow) in the presence of the four deoxynucleotide triphosphates (dNTPs) using incubation times of about 15 to 25 min at 20 to 25°C in 50 mM Tris pH 7.6, 50 mM NaCl, 6 mM MgCl₂, 6 mM DTT and 5-10 μM dNTPs. The Klenow fragment fills in at 5′ sticky ends but chews back protruding 3′ single strands, even though the four dNTPs are present. If desired, selective repair can be performed by supplying only one of the, or selected, dNTPs within the limitations dictated by the nature of the sticky ends. After treatment with Klenow, the mixture is extracted with phenol/chloroform and ethanol precipitated. Treatment under appropriate conditions with S1 nuclease or Bal-31 results in hydrolysis of any single-stranded portion.

Synthetic oligonucleotides are prepared by the method of Efimov, V.A., et al (Nucleic Acids Res (1982) 6875-6894), and can be prepared using commercially available automated oligonucleotide synthesizers. Kinasing of single strands prior to annealing or for labeling is achieved using an excess, e.g., approximately 10 units of polynucleotide kinase to 1 nmole substrate in the presence of 50 mM Tris, pH 7.6, 10 mM MgCl₂, 5 mM dithiothreitol, 1-2 mM ATP, 1.7 pmoles γ32P-ATP (2.9 mCi/mmole), 0.1 mM spermidine, 0.1 mM EDTA.

Ligations are performed in 15-50 μl volumes under the following standard conditions and temperatures: 20 mM Tris-Cl pH 7.5, 10 mM MgCl₂, 10 mM DTT, 33 μg/ml BSA, 10 mM-50 mM NaCl, and either 40 μM ATP, 0.01-0.02 (Weiss) units T4 DNA ligase at 0°C.
(for "sticky end" ligation) or 1 mM ATP, 0.3-0.6 (Weiss) units T4 DNA ligase at 14°C (for "blunt end" ligation). Intermolecular "sticky end" ligation are usually performed at 33-100 µg/ml total DNA concentrations (5-100 nM total end concentration). Intermolecular blunt end ligations (usually employing a 10-30 fold molar excess of linkers) are performed at 1 µM total ends concentration.

In vector construction employing "vector fragments", the vector fragment is commonly treated with bacterial alkaline phosphatase (BAP) or calf intestinal alkaline phosphatase (CIP) in order to remove the 5' phosphate and prevent religation of the vector. Digestions are conducted at pH 8 in approximately 150 mM Tris, in the presence of Na⁺ and Mg²⁺ using about 1 unit of BAP or CIP per µg of vector at 60°C for about one hour. In order to recover the nucleic acid fragments, the preparation is extracted with phenol/chloroform and ethanol precipitated.

Alternatively, religation can be prevented in vectors which have been double digested by additional restriction enzyme digestion of the unwanted fragments.

For portions of vectors derived from cDNA or genomic DNA which require sequence modifications, site specific primer directed mutagenesis is used. This is conducted using a primer synthetic oligonucleotide complementary to a single stranded phage DNA to be mutagenized except for limited mismatching, representing the desired mutation. Briefly, the synthetic oligonucleotide is used as a primer to direct synthesis of a strand complementary to the phage, and the resulting double-stranded DNA is transformed into a phage-supporting host bacterium. Cultures of the transformed bacteria are plated in top agar, permitting
plaque formation from single cells which harbor the phage.

Theoretically, 50% of the new plaques will contain the phage having, as a single strand, the mutated form; 50% will have the original sequence. The resulting plaques are hybridized with kinased synthetic primer at a temperature which permits hybridization of an exact match, but at which the mismatches with the original strand are sufficient to prevent hybridization. Plaques which hybridize with the probe are then picked, cultured, and the DNA recovered.

E.4. Verification of Construction

E.5. **cDNA or Genomic Library Production**

Human genomic libraries are constructed in λ phage as is known in the art. See, e.g., Maniatis, T., et al. *Cell* (1978) **15**: 687-701. cDNA libraries can be prepared as described above in λgt11 phage, or double-stranded cDNA synthesized from mRNA isolated using standard techniques can be prepared for insertion into a plasmid vector such as pBR322 using homopolymeric tailing mediated by calf thymus terminal transferase (Sutcliffe, J.G., *Nucleic Acid Res* (1978) **5**:2721-2732).

First strand cDNA is synthesized by the RNA-dependent DNA polymerase from Avian Myeloblastosis Virus, by priming with oligo (dT) 12-18 on 5 µg mRNA. The RNA template is then liberated from the nascent DNA strand by denaturation at 100°C for 5 min, followed by chilling on ice. Second strand DNA is synthesized by using the large fragment of DNA polymerase I of *E. coli*, relying on self-priming at the 3'-end of the first strand molecule, thereby forming a double-stranded hairpin DNA. These molecules are blunt-ended at the open-ended termini, and the hairpin loop is cleaved open with S1 nuclease from *Aspergillus oryzae*. S1 nuclease digestion of the double-stranded cDNA takes place in 300 mM NaCl, 30 mM NaOAc, pH 4.5, 3 mM ZnCl₂ for 30 min at 37°C with 600 units enzyme. The cDNA is extracted with phenol:chloroform, and small oligonucleotides are removed by three ethanol precipitations in the presence of ammonium acetate. This is done as follows: a half volume of 7.5 M ammonium acetate and two volumes ethanol are added to the cDNA solution, which is precipitated at -70°C. The blunt-ended, double-stranded cDNA is then fractionated by size using gel filtration through a column (0.3 x 14 cm) Sepharose 4B (Pharmacia Fine Chemicals, Piscataway, NJ) or by ultracentrifugation in
5-20% glycerol gradient followed by fractionation of the gradient. cDNA roughly greater than the desired length, e.g., 300 base pairs is retained and recovered by precipitation with 70% ethanol. Short (10-30 nucleotides) polymeric tails of deoxycytosine are added to the 3' termini of the cDNA using a reaction containing 0.2 M potassium cacodylate, 25 mM Tris, pH 6.9, 2 mM dithiothreitol, 0.5 mM CoCl₂, 200 mM dTTP, 400 µg/ml BSA, and 40 units calf thymus terminal deoxynucleotidyl transferase for 5 min at 22°C. The reaction is extracted with phenol:chloroform, and small oligonucleotides are removed with three ethanol precipitations in the presence of ammonium acetate.

The tailed cDNA is annealed with a host vector such as pBR322 which has been cleaved with, for example, PstI and tailed with oligo dG. In one operable embodiment 2.5 µg pBR322-dG DNA is annealed with the cDNA at a vector concentration of 5 µg/ml, and the hybrids are transferred into E. coli MC1061 by the CaCl₂-treatment described by Casabdan, M., et al., Mol Biol (1980) 138:179-207.

E.6. Probing cDNA or Genomic Libraries
cDNA or genomic libraries may be screened if desired using the colony or plaque hybridization procedures. Colonies or plaques are replicated onto duplicate nitrocellulose filter papers (S & S type BA-85) and colonies are allowed to grow at 37°C for 14-16 hr on L agar containing 15 µg/ml tetracycline. The colonies are lysed with 10% SDS and the DNA is fixed to the filter by sequential treatment for 5 min with 500 mM NaOH/1.5 M NaCl, then 0.5 M Tris HCl (pH 8.0)/1.5 M NaCl followed by 2 x standard saline citrate (SSC). Filters are air dried and baked at 80°C for 2 hr.
For nick-translated probe, the duplicate filters are prehybridized at 42°C for 16-18 hr with 10 ml per filter of DNA hybridization buffer (50% formamide (40% formamide if reduced stringency), 5 x SSC, pH 7.0, 5x Denhardt's solution (polyvinylpyrrolidone, plus Ficoll and bovine serum albumin; 1 x = 0.02% of each), 50 mM sodium phosphate buffer at pH 7.0, 0.2% SDS, 50 μg/ml yeast tRNA, and 50 μg/ml denatured and sheared salmon sperm DNA).

Samples are hybridized with nick-translated DNA probes at 42°C for 12-36 hr for homologous species and 37°C for heterologous species contained in 5 ml of this same DNA hybridization buffer. The filters are washed two times for 30 min, each time at 50°C, in 0.2 x SSC, 0.1% SDS for homologous species hybridization, and at 50°C in 3 x SSC, 0.1% SDS for heterologous species hybridization. Filters are air dried and autoradiographed for 1-3 days at -70°C.

For synthetic (15-30 mer) oligonucleotide probes, the duplicate filters are prehybridized at 42°C for 2-8 hr with 10 ml per filter of oligo-hybridization buffer (6 x SSC, 0.1% SDS, 1 mM EDTA, 5x Denhardt's, 0.05% sodium pyrophosphate and 50 μg/ml denatured and sheared salmon sperm DNA).

The samples are hybridized with kinased oligonucleotide probes of 15-30 nucleotides under conditions which depend on the composition of the oligonucleotide. Typical conditions employ a temperature of 30-42°C for 24-36 hr with 5 ml/filter of this same oligo-hybridization buffer containing probe. The filters are washed two times for 15 min at 23°C, each time with 6 x SSC, 0.1% SDS and 50 mM sodium phosphate buffer at pH 7, then are washed once for 2 min at the calculated hybridization temperature with 6 x SSC
and 0.1% SDS, air dried, and are autoradiographed at -70°C for 2 to 3 days.

If the amino acid sequence of the desired protein or nucleotide sequence encoding it in mRNA is known, the DNA for insertion into the host vectors of the invention may be obtained either by synthetic means, or, if vectors containing such sequences are on deposit or available, by cloning such vectors. For synthesis of the coding sequences, alternating sense and anti-sense overlapping single stranded oligonucleotides are prepared, and the alternating sense and anti-sense single stranded portions filled in enzymatically by treating with DNA polymerase and dNTPs. The oligomers are prepared by the method of Efimov, V.A., et al (Nucleic Acids Res (1982) 6875-6894), and can be prepared using commercially available automated oligonucleotide synthesizers. Kinasing of single strands prior to annealing or for labeling is achieved using an excess, e.g., approximately 10 units of polynucleotide kinase to 1 nmole substrate in the presence of 50 mM Tris, pH 7.6, 10 mM MgCl₂, 5 mM dithiothreitol, 1-2 mM ATP, 1.7 pmoles γ32P-ATP (2.9 mCi/nmole), 0.1 mM spermidine, 0.1 mM EDTA.

E.7. Hosts Exemplified

Host strains used in cloning and expression herein are as follows:

For cloning and sequencing, and for expression of construction under control of most bacterial promoters, E. coli strain MC1061 was used.

The cells used for mammalian expression are Chinese hamster ovary (CHO) cells.
Claims

1. Human phospholipase inhibitory protein (hPIP) in substantially pure form.

2. The hPIP of claim 1 which has a primary amino acid sequence having 40% homology to that shown for the mature protein in Figure 13.

3. The hPIP of claim 1 in the form of a complex to apolipoprotein AIV (apoAIV).

4. An active PIP fragment, wherein the PIP amino acid sequences are similar in secondary structure to that of the active PIP fragment encoded by nucleotides 490-852 of Figure 13.

5. The active PIP fragment of claim 4 which is encoded by the PIP encoding insert of any of the vectors selected from the group consisting of pTRP-PIP(F), pTRP-PIP(F-), pTRP-PIP(F/A) and pTRP-PIP(465-852).

6. A method of purifying the hPIP/apoAIV complex of claim 3 which comprises:
   (a) treating human interperitoneal dialysis fluid with 40-60% ammonium sulfate to obtain a precipitate;
   (b) subjecting the precipitate to Affi-gel B to obtain an unbound fraction;
   (c) treating the unbound fraction of (b) with concanavalin-A sepharose to obtain an unbound fraction;
(d) subjecting the unbound fraction of (c) to anionic exchange chromatography at pH 7-9 to obtain an active fraction;

(e) treating the active fraction from (d) by preparative SDS-PAGE to obtain a 40 kd fraction;

(f) recovering and reconstituting the 40 kd fraction of (e).

7. The hPIP/apoAIV complex protein obtained by the process of claim 6.

8. A method of purifying the hPIP of claim 1, which comprises:

(a) treating human interperitoneal dialysis fluid with 40-60% ammonium sulfate to obtain a precipitate;

(b) subjecting the precipitate to Affi-gel B to obtain an unbound fraction;

(c) treating the unbound fraction of (b) with concanavalin-A sepharose to obtain an unbound fraction;

(d) subjecting the unbound fraction of (c) to anionic exchange chromatography at pH 7-9 to obtain an active fraction;

(e) dialyzing the active fraction of (d) against pH 5.5 sodium citrate to obtain a precipitate and a supernatant, and

(f) recovering the supernatant of (e).

9. The hPIP protein obtained by the process of claim 8.

10. Antibodies prepared against the protein of claim 7 or 9.
11. Recombinantly produced human phospholipase inhibitory protein (hPIP).

12. The hPIP of claim 11 which has a primary amino acid sequence having 40% homology to that shown for the mature protein in Figure 13.

13. A recombinant expression system for hPIP which system comprises a DNA sequence encoding hPIP operably linked to control sequences compatible with a recombinant host.

14. The expression system of claim 13 wherein the coding sequences encode a protein having a primary amino acid sequence having 40% homology to that shown for the mature protein in Figure 13.

15. The expression system of claim 13 wherein the coding sequences encode a protein having the amino acid sequence of Figure 13.

16. A recombinant expression system for the active hPIP fragment of claim 4 which system comprises a DNA sequence encoding said active hPIP fragment operably linked to control sequences compatible with a recombinant host.

17. The expression system of claim 13 or 16 which is disposed on a vector for transformation.

18. Recombinant host cells transformed with the expression system of claim 13 or 16.
19. hPIP prepared by culturing the cells of claim 18.

20. A method of producing human PIP which comprises culturing the cells of claim 18.

21. A pharmaceutical composition for the treatment of inflammatory conditions in mammals which comprises a therapeutically effective amount of the hPIP of claim 1-5 in admixture with at least one pharmaceutically acceptable excipient.

22. A method for treating inflammation in mammals which method comprises administering to a subject in need of such treatment a therapeutically effective amount of, or pharmaceutical composition containing a therapeutically effective amount of, the hPIP of claim 1-5.

### Observations Where Certain Claims Were Found Unsearchable

This international search report has not been established in respect of certain claims under Article 17(2) (a) for the following reasons:

1. Claim numbers ....... because they relate to subject matter not required to be searched by this Authority, namely: 

2. Claim numbers ........... because they relate to parts of the international application that do not comply with the prescribed requirements to such an extent that no meaningful international search can be carried out, specifically: 

### Observations Where Unity of Invention Is Lacking

This International Searching Authority found multiple inventions in this international application as follows:

1. Claims 1-9, 11, 12 and 19
2. Claims 10
3. Claims 13-18 and 20
4. Claims 21 and 22

1. As all required additional search fees were timely paid by the applicant, this international search report covers all searchable claims of the international application.

2. As only some of the required additional search fees were timely paid by the applicant, this international search report covers only those claims of the international application for which fees were paid, specifically claims:

3. No required additional search fees were timely paid by the applicant. Consequently, this international search report is restricted to the invention first mentioned in the claims; it is covered by claim numbers:

4. As all searchable claims could be searched without effort justifying an additional fee, the International Searching Authority did not invite payment of any additional fee.

**Remark on Protest**

- The additional search fees were accompanied by applicant's protest.
- No protest accompanied the payment of additional search fees.
