A temperature control system in a liquid cooled internal combustion engine equipped with a radiator controls the state of a flow control valve for controlling flow of a temperature control fluid through a passageway in the engine. Sensors detect an engine condition temperature, such as engine oil temperature. The sensors preferably also detect the temperature of the temperature control fluid and the temperature of the ambient air. An engine computer receives signals from the sensors and compares the signals to one or more predetermined values. In one embodiment, the engine computer compares the engine oil temperature signal to a predetermined value to control actuation of the valve. In another embodiment, the engine computer adjusts a predetermined temperature control fluid temperature value based on the comparison of the engine oil temperature signal to the predetermined engine oil temperature value. The engine computer then compares the temperature control fluid temperature signal to the adjusted temperature control fluid temperature. The engine computer actuates the flow control valve based on the comparison of the temperature control fluid temperature signal to the adjusted temperature control fluid temperature. The predetermined engine oil temperature value and predetermined temperature control fluid temperature value preferably vary with ambient air temperature.

SYSTEM FOR MAINTAINING ENGINE OIL
AT AN OPTIMUM TEMPERATURE

Cross-Reference to Related Application

This application is a related to PCT Application Serial Number PCTUS95/11742, filed 12 September 1995 and entitled "SYSTEM FOR CONTROLLING THE FLOW OF TEMPERATURE CONTROL FLUID." The entire disclosure of this application is incorporated herein by reference.

Field of the Invention

This invention relates to a system for maintaining engine lubrication oil at a desired temperature by controlling the state of one or more flow control valves which regulate the flow of temperature control fluid within an internal combustion gasoline or diesel engine equipped with a radiator.

Background of the Invention

Page 169 of the Goodheart-Willcox Automotive Encyclopedia. The Goodheart-Willcox Company, Inc., South Holland, Illinois, 1995 describes that as fuel is burned in an internal combustion engine, about one-third of the heat energy in the fuel is converted to power. Another third goes out the exhaust pipe unused, and the remaining third must be handled by a cooling system. This third is often underestimated and even less understood.

Most internal combustion engines employ a pressurized cooling system to dissipate the heat energy generated by the combustion process. The cooling system circulates water or liquid coolant through a water jacket which surrounds certain parts of the engine (e.g., block, cylinder, cylinder head, pistons). The heat energy is transferred from the engine parts to the coolant in the water jacket. In hot ambient air
temperature environments, or when the engine is working hard, the transferred heat energy will be so great that it will cause the liquid coolant to boil (i.e., vaporize) and destroy the cooling system. To prevent this from happening, the hot coolant is circulated through a radiator well before it reaches its boiling point. The radiator dissipates enough of the heat energy to the surrounding air to maintain the coolant in the liquid state.

In cold ambient air temperature environments, especially below zero degrees Fahrenheit (-17.8 °C), or when a cold engine is started, the coolant rarely becomes hot enough to boil. Thus, the coolant does not need to flow through the radiator. Nor is it desirable to dissipate the heat energy in the coolant in such environments since internal combustion engines operate most efficiently and pollute the least when they are running relatively hot. A cold running engine will have significantly greater sliding friction between the pistons and respective cylinder walls than a hot running engine because oil viscosity decreases with temperature. A cold running engine will also have less complete combustion in the engine combustion chamber and will build up sludge more rapidly than a hot running engine. In an attempt to increase the combustion when the engine is cold, a richer fuel is provided. All of these factors lower fuel economy and increase levels of hydrocarbon exhaust emissions.

To avoid running the coolant through the radiator, coolant systems employ a thermostat. The thermostat operates as a one-way valve, blocking or allowing flow to the radiator. Fig. 2 of U.S. Patent No. 4,545,333 shows a typical prior art thermostat controlled coolant systems. Most prior art coolant systems employ wax pellet type or bimetallic coil type thermostats. These thermostats are self-contained devices which open and close according to precalibrated temperature values.

Practical design constraints limit the ability of the coolant system to adapt to a wide range of operating environments. For example, the heat removing capacity is limited by the size of the radiator and the volume and speed of coolant flow. The state of the self-contained prior art wax pellet type or bimetallic coil type thermostats is controlled solely by coolant temperature. Thus, other factors such as ambient air temperature cannot be taken into account when setting the state of such thermostats.
Numerous proposals have been set forth in the prior art to more carefully tailor the coolant system to the needs of the vehicle and to improve upon the relatively inflexible prior art thermostats.

U.S. Patent No. 5,121,714 discloses a system for directing coolant into the engine in two different streams when the oil temperature is above a predetermined value. One stream flows through the cylinder head and the other stream flows through the cylinder block. When the oil temperature is below the predetermined value, a flow control valve closes off the stream through the cylinder block. The flow control valve is connected to an electronic control unit (ECU). The ECU sends control signals to the flow control valve and to other engine cooling system components. U.S. Patent No. 5,121,714 also employs a typical prior art thermostat valve 108 for directing the cooling fluid through a radiator when its temperature is above a preselected value. This patent also describes that the thermostat valve can be replaced by an electrical-control valve, although no specific examples are disclosed.

U.S. Patent No. 4,744,336 discloses a solenoid actuated piston type flow control valve for infinitely varying coolant flow into a servo controlled valve. The solenoids receive pulse signals from an electronic control unit (ECU). The ECU receives inputs from sensors measuring ambient temperature, engine input and output coolant temperature, combustion temperature, manifold pressure and heater temperature.

The goal of all engine cooling systems is to maintain the internal engine temperature as close as possible to a predetermined value. Since engine coolant temperature generally tracks internal engine temperature, the prior art approach to controlling internal engine temperature control is to control engine coolant temperature. Many problems arise from this approach. For example, sudden load increases on an engine may cause the internal engine temperature to significantly exceed the optimum value before the coolant temperature reflects this fact. If the thermostat is in the closed state just before the sudden load increase, the extra delay in opening will prolong the period of time in which the engine is unnecessarily overheated.

Another problem occurs during engine start-up or warm-up. During this period of time, the coolant temperature rises more rapidly than the internal engine temperature. Since the thermostat is actuated by coolant temperature, it often opens
before the internal engine temperature has reached its predetermined value, thereby causing coolant in the water jacket to prematurely cool the engine. Still other scenarios exist where the engine coolant temperature cannot be sufficiently regulated to cause the desired internal engine temperature.

When the internal engine temperature is not maintained at an optimum value, the engine oil will also not be at the optimum temperature. Engine oil life is largely dependent upon wear conditions. Engine oil life is significantly shortened if an engine is run either too cold or too hot. As noted above, a cold running engine will have less complete combustion in the engine combustion chamber and will build up sludge more rapidly than a hot running engine. The sludge contaminates the oil. A hot running engine will prematurely break down the oil. Thus, more frequent oil changes are needed when the internal engine temperature is not consistently maintained at its optimum value.

Prior art cooling systems also do not account for the fact that the optimum oil temperature varies with ambient air temperature. As the ambient air temperature declines, the internal engine components lose heat more rapidly to the environment and there is an increased cooling effect on the internal engine components from induction air. To counter these effects and thus maintain the internal engine components at the optimum operating temperature, the engine oil should be hotter in cold ambient air temperatures than in hot ambient air temperatures. Current prior art cooling systems cannot account for this difference because the cooling system is responsive only to coolant temperature.

In sum, the prior art approach of employing coolant temperature to control the internal engine temperature is crude and inaccurate. Accordingly, despite the large number of ideas proposed to improve the performance of engine cooling systems, there is still a need for cooling system which more effectively matches its performance to the instantaneous needs of the engine, while still meeting the plurality of other functions noted above which are demanded of the cooling system. There is especially a need for a system and technique for controlling the state of one or more flow control valves in engine cooling systems in accordance with predetermined engine
and ambient temperature conditions, including the actual internal engine temperature. The present invention fills that need.

**Summary of the Invention**

A temperature control system in a liquid cooled internal combustion engine equipped with a radiator controls the state of a flow control valve for controlling flow of a temperature control fluid through a passageway in the engine. A sensor detects an engine condition temperature, such as the temperature of the engine oil. A sensor also preferably detects the temperature of the temperature control fluid and the temperature of the ambient air. An engine computer receives signals from the sensors and compares the signals to predetermined values. In one embodiment, the engine computer compares the engine oil temperature signal to a predetermined value to control actuation of the valve.

In another embodiment, the engine computer compares the engine oil temperature signal to a predetermined engine oil temperature value. The engine computer adjusts a predetermined temperature control fluid temperature value based on the comparison of the engine oil temperature signal to the predetermined engine oil temperature value. The engine computer then compares the temperature control fluid temperature signal to the adjusted temperature control fluid temperature. The engine computer actuates the flow control valve based on the comparison of the temperature control fluid temperature signal to the adjusted temperature control fluid temperature.

The predetermined engine oil temperature value and predetermined temperature control fluid temperature value preferably vary with ambient air. Accordingly, the engine computer determines the predetermined value by comparing the sensed ambient air temperature to one or more sets of values defining a curve.

The foregoing and other objects features and advantages of the present invention will become more apparent in light of the following detailed description of the preferred embodiments thereof, as illustrated in the accompanying drawings.

**Brief Description of the Drawings**
For the purpose of illustrating the invention, there is shown in the drawings a form which is presently preferred; it being understood, however, that this invention is not limited to the precise arrangements and instrumentalities shown.

Fig. 1 is a top plan view of one preferred form of a hydraulically operated electronic engine temperature control valve for controlling the flow of temperature control fluid in an engine.

Fig. 2 is a sectional side view of the valve in Fig. 1, taken along line 2-2 in Fig. 1.

Fig. 3 is a different sectional side view of the valve in Fig. 1, taken along line 3-3 in Fig. 1.

Fig. 4 is yet another sectional side view of the valve in Fig. 1, taken along line 4-4 in Fig. 1.

**Description of the Preferred Embodiment**

While the invention will be described in connection with a preferred embodiment, it will be understood that it is not intended to limit the invention to that embodiment. On the contrary, it is intended to cover all alternatives, modifications and equivalents as may be included within the spirit and scope of the invention as defined by the appended claims.
Certain terminology is used herein for convenience only and is not be taken as a limitation on the invention. Particularly, words such as "upper," "lower," "left," "right," "horizontal," "vertical," "upward," and "downward" merely describe the configuration shown in the figures. Indeed, the valves and related components may be oriented in any direction. For example while a vertically oriented radiator is illustrated in the figures, a horizontally oriented radiator is well within the scope of the invention.

Apparatus depicting the preferred embodiments of the novel electronic engine temperature control valve are illustrated in the drawings.

Fig. 1 shows a top plan view of an electronic engine temperature control valve 10 (hereafter, "EETC valve 10") as it would appear attached to an engine temperature control fluid passageway 12. (Only a portion of the passageway 12 is visible in this view.) The EETC valve 10 is attached to the passageway 12 by mounting bolts 14. The EETC valve 10 includes two major subcomponents, a valve mechanism 16 and a pair of solenoid actuated hydraulic fluid injectors 18 and 20. The injector 18 is a fluid inlet valve and the injector 20 is a fluid outlet valve. In effect, the injectors 18, 20 are one-way flow through valves. The view in Fig. 1 shows valve housing sub-parts including housing 22 of the valve mechanism 16 and housings 24 and 26 of the respective hydraulic fluid injectors 18 and 20. The EETC valve 10 also includes fluid pressure sensor 28 mounted to the valve housing through insert 30. In the preferred embodiment, the insert 30 is a brass fitting.

Also visible in Fig. 1 are electrical terminals 32, 34, and fluid inlet and outlet tubes 36, 38, associated with respective fluid injectors 18 and 20. These tubes are attached to respective solid tubes which feed into the valve housing through inserts 30. Those inserts 30 are not visible in this view. However, the insert 30 associated with the inlet tube 36 is visible in Fig. 3. The inlet tube 36 is connected to a source of pressurized hydraulic fluid, such as engine lubrication oil. The outlet tube 38 is connected to a low pressure reservoir of the hydraulic fluid, such as an engine lubrication oil pan. Each of the electrical terminals 32, 34 are connected at one end to a solenoid inside of its respective fluid injector (not shown) and at the other end to a computerized engine electronic control unit (ECU) (not shown).
Fig. 2 shows a sectional side view of one version of the EETC valve 10, taken along line 2-2 in Fig. 1. In this version, the EETC valve 10 is a hydraulically actuated diaphragm valve 40. The diaphragm valve 40 reciprocates within the valve housing 22 along axis A between a first and second state or position. The solid lines in Fig. 2 shows the valve 40 in the first position which is associated with a valve "closed" state. Fig. 2 also shows the valve's second position in phantom which is associated with a valve "open" state. In the first "closed" position, the valve 40 prevents flow of temperature control fluid (hereafter, "TCF") through passageway opening 42. In the second "open" position, the valve 40 allows fluid flow through the opening 42. The opening 42 leads to the engine radiator (not shown). Also visible in Fig. 2 is the electrical terminal 34 and the outlet tube 38 associated with the solenoid 20, the fluid pressure sensor 28, and one of the mounting bolts 14.

The temperature control fluid (TCF) referred to herein is typically known in the art as "coolant." Coolant is a substance, ordinarily fluid, used for cooling any part of a reactor in which heat is generated. However, as will be described below, the TCF not only removes heat energy from engine components but is also employed in certain embodiments to deliver heat energy to certain engine components. Thus, the TCF is more than merely a coolant. Likewise, while the prior art referenced herein relates to engine cooling systems, the invention herein employs its unique valve(s) in an engine temperature control system, providing both cooling and heating functions to engine components.

Turning again to Fig. 2, the valve 40 reciprocates within the valve mechanism housing 22. The housing 22 is constructed of body 44 and cover 46, held together by band clamp or crimp 48. The body 44 includes a generally horizontal dividing wall 50 which divides the body 44 into upper compartment 52 and lower compartment 54. (It should be recognized that the dividing wall 50 is a generally cylindrical disk in three dimensions.) The center of the dividing disk or wall 50 has a circular bore to allow passage of a reciprocating valve shaft or rod therethrough, as described below. A cylindrical collar 56 extends vertically upward and downward from the inner edge of the dividing wall 50, thereby coinciding with the outer circumference
of the circular bore. The collar 56 is integral with the dividing wall 50. The lower end of the lower compartment 54 leads to the opening 42.

As noted above, the valve 40 reciprocates between a first "closed" position wherein the valve 40 prevents flow of TCF through passageway opening 42 and a second "open" position wherein the valve 40 allows fluid flow through the opening 42. When the valve 40 is "closed," the water pump circulates the TCF only through the engine block water jacket. If the heater or defroster is in operation, the fluid is also circulated through a heat exchanger for the passenger compartment heater, typically a heater core. When the valve 40 is "open," most of the TCF flows through the radiator before it is circulated through the engine block water jacket and the heater's heat exchanger.

Thus, in the embodiment of the invention shown in Fig. 2, the valve 40 functions in a manner similar to the prior art wax pellet thermostat. However, unlike the fixed temperature wax pellet thermostat, the valve 40 is electronically controlled and thus can be opened and closed according to a computer controlled signal tailored to specific engine operating conditions and ambient environmental conditions.

The diaphragm valve 40 includes upper chamber 58, diaphragm 60, plate 62, lower chamber 64, shaft or rod 66, valve member 68 and biasing spring 70. The diaphragm 60, plate 62 and spring 70 are disposed in the housing body's upper compartment 52. The diaphragm 60 separates the housing body's upper compartment 52 into the upper and lower chambers 58, 64. The spring 70 is seated on one side against a lower surface of the plate 62 and on the other side against an upper surface of the housing body's dividing wall 50. The rod 66 is also seated on one side against the lower surface of the plate 62 and extends through the housing body's upper and lower compartments 52, 54. The diaphragm 60 is mechanically linked to the valve member 68 through the plate 62 and the rod 66. The position of the diaphragm 60 is thus communicated through the plate 62 and the rod 66 to the valve member 68, thereby causing the valve member 68 to reciprocate between the first and second positions, shown in solid and in phantom, respectively.

The lower chamber portion of the body 44 includes air bleed opening 72 therethrough for removing and reintroducing air into the lower chamber 64 as the
diaphragm valve 40 is moved between its first and second positions. Radial O-ring 74 prevents the hydraulic fluid from leaking out of passage 76.

The valve 40 also includes a gasket seal 78 around the periphery of the opening 42 to allow the valve member 68 to close off flow through the opening 42 when the valve 40 is in the first position. In the preferred embodiment of the invention, the gasket seal 78 also functions as the valve seat for the valve member 68. The gasket seal 78 is generally square in vertical cross-section, although other shapes are contemplated by the invention. One preferred type of gasket seal material is Viton®, manufactured by E.I. Du Pont De Nemours & Co., Wilmington, DE. An O-ring 80 is disposed within the outer circumference of the rod 80 to prevent TCF in the lower compartment 54 from leaking into the valve’s lower chamber 64.

In the preferred embodiment of the invention, the diaphragm 60 possesses special characteristics to allow it to more easily withstand very high pressures. Details of the diaphragm 60 are more fully discussed with respect to Fig. 15.

The diaphragm valve upper chamber 58 is in fluid communication with hydraulic fluid passageway 82 through opening 84 therebetween. The fluid passageway 82 is in fluid communication with the outlet of the hydraulic fluid injector 18 and the inlet of the hydraulic fluid injector 20 through the passage 76, as best shown in Fig. 4. The fluid passageway is also in fluid communication with the fluid pressure sensor 28 to allow the pressure in the passageway to be monitored for controlling the valve state. Diaphragm valves of the size suitable for installation in an engine fluid passageway can typically withstand pressures in the range of 200 psi (1378.9 kPa). The diaphragm strength is typically the first component to fail due to excessive high pressure. Pressure monitoring helps to ensure that pressures do not exceed those which the valve components can safely handle.

A warning system can be incorporated which would send a signal from the pressure sensor 28 to the ECU when the pressure exceeds or falls below a predetermined limit, such as if there is a loss of hydraulic pressure. The ECU could then display a suitable warning to the operator. Additionally, override mechanisms, such as an electro-mechanical device, could be activated to lock the EETC valve in the open position thereby maintaining flow to the radiator during valve failure.
In the preferred embodiment of the invention, the diaphragm includes certain features to allow it to better withstand a high pressure environment. Fig. 15 shows a preferred diaphragm and an exploded view of the preferred manner in which the diaphragm is mounted in the diaphragm valve mechanism housing to achieve the best results under high pressure.

Unlike prior art diaphragm valves, such as disclosed in U.S. Patent No. 4,484,541, which are actuated and deactuated by applying and removing a vacuum to and from an upper chamber, the diaphragm valve 40 disclosed herein is preferably actuated by pressurized and depressurizing the upper chamber 58 with hydraulic fluid. A hydraulic fluid system has numerous advantages over a vacuum actuated system including less sensitivity to temperature extremes, and increased accuracy, durability and reliability. These are very considerations since the EETC system must function under a multitude of extreme conditions, both environmental and physical. Accordingly, a reliable power source is required and one of the most dependable sources of hydraulic fluid in an engine is pressurized engine oil.

The EETC internal engine circuit is generally operating at higher temperatures to optimize engine performance. These higher temperatures require higher pressures to actuate the EETC valve (e.g., about 10 pounds of force). Standard electromechanical solenoid-type or vacuum-type valves may experience operational problems during the worst case conditions. The novel EETC valve of the present invention is designed to provide the force required to actuate the valve when less than 50% of normal engine oil pressure is available, such as when there is a low amount of oil present, a high oil temperature, or the oil pump is worn. Accordingly, the hydraulically actuated EETC valve disclosed is the preferred valve for the disclosed system.

In operation, the valve 40 functions as follows. When the engine is operating and it is desired to open the valve 40, the ECU sends a control signal to the solenoid of the hydraulic fluid injector 18 to open the injector's valve. Simultaneously, the ECU sends a control signal to the solenoid of the hydraulic fluid injector 20 to close that injector's valve, if it is not already closed. Pressurized hydraulic fluid from the fluid inlet tube 36 flows through the fluid injector 18, the hydraulic fluid passageway 82, the opening 84 and into the valve upper chamber 58, where it pushes against the
diaphragm 60 and plate 62. When the fluid pressure against the diaphragm 60 and plate 62 exceeds the opposing force of the biasing spring 70, the diaphragm 60 moves downward, thereby causing the valve member 68 to move downward. The upper chamber 58 expands as the diaphragm 60 and plate 62 moves downward. As the upper chamber 58 fills with fluid, the pressure in the chamber rises. When the pressure sensor 28 detects that the fluid pressure has reached a predetermined level, it causes the ECU to start a timer which runs for a predetermined period of time. After that time has expired, the ECU sends a control signal to the solenoid of the hydraulic fluid injector 18 to close the injector’s valve. The hydraulic fluid in the upper chamber 58 thus remains trapped therein.

The predetermined pressure level and time period are empirically determined so as to allow the valve member 68 to reach its open or second position. To avoid excessively activating the injector’s solenoids, the open injector valve should be closed as soon as the diaphragm valve 40 has reached the desired state. Also, a diaphragm valve 40 is selected which will always open under less pressure than exists in the hydraulic fluid system that the inlet fluid injector 18 is attached to. To remove air trapped in the upper chamber 58 and/or connected passageways, the ECU can be programmed to open the valve of the outlet fluid injector 20 for a short period of time (e.g., one second). This is similar to the technique for bleeding air from a vehicle’s hydraulic braking system.

If hydraulic fluid leaks out of the upper chamber 58, the pressure sensor 28 will immediately sense this condition. The ECU responds by again sending a control signal to the solenoid of the hydraulic fluid injector 18 to open the injector’s valve. When the pressure sensor 28 detects that the fluid pressure has again reached the predetermined level, it causes the ECU to start a timer which runs again for a predetermined period of time. After that time has expired, the ECU sends a control signal to the solenoid of the hydraulic fluid injector 18 to close the injector’s valve.

The process of opening the EETC valve is automatically delayed by the ECU during engine start-up until the source of the hydraulic fluid pressure reaches its normal operating level. In one embodiment of the invention which employs engine
lubrication oil as the hydraulic fluid, the delay period is about two or three seconds to allow for lubrication of all critical engine components.

When it is desired to close the valve 40, the above steps are reversed. That is, the ECU sends a control signal to the solenoid of the hydraulic fluid injector 18 to close the injector's valve, if it is not already closed. Simultaneously, the ECU sends a control signal to the solenoid of the hydraulic fluid injector 20 to open that injector's valve. The pressurized hydraulic fluid inside the upper chamber 58 flows out of the upper chamber 58 through the opening 84, into the hydraulic fluid passageway 82, through the open valve of the hydraulic fluid injector 20 and into the fluid outlet tube 38. The fluid outlet tube 38 connects to a reservoir (not shown) of hydraulic fluid. As the hydraulic fluid emptied out of the upper chamber 58, biasing spring 70 pushes the diaphragm 60 and plate 62 upward, thereby causing the valve member 68 to move upward until the valve 40 becomes closed. When the pressure sensor 28 detects that the upper chamber 58 is no longer pressurized, it causes the ECU to send a control signal to the solenoid of the hydraulic fluid injector 20 to close that injector's valve.

The vehicle's engine does not need to be operating to close the valve 40. Thus, during a "hot engine off soak" (i.e., the time period subsequent to shutting off a hot engine), the valve 40 stays open since the hydraulic fluid remains trapped in the upper chamber 58. This function mimics prior art cooling systems which maintain an open path to the radiator until the thermostat’s wax pellet rehardens. After the engine has cooled down, the ECU (which is powered from the vehicle’s battery) causes the valve 40 to close, as described above.

Fig. 3 shows a different sectional side view of the diaphragm version of the EETC valve 10, taken along line 3-3 in Fig. 1. This view more clearly shows the entire path of the TCF from a passageway leading from the engine block water jacket, through the valve 40 and to the radiator. As noted above, if the valve 40 is closed, the TCF circulates directly back into the engine block water jacket, without being diverted into the radiator.

Fig. 3 also shows the inlet hydraulic fluid injector 18 and the fluid inlet tube 36 leading thereto, along with the insert 30 associated therewith. As noted above, the insert 30 is preferably a brass fitting. The passageway 82 from the outlet of the
injector's valve to the upper chamber 58 is not visible in this view but is clearly shown in Fig. 4. The fluid connection or path between the fluid inlet tube 36 and the injector 18 is also not visible in this view but is understandable with respect to Fig. 6.

Fig. 4 shows yet another sectional side view of the diaphragm version of the EETC valve 10, taken along line 3-3 in Fig. 1. This view shows fluid passageway 86 from the outlet of the hydraulic fluid injector 18 to the passage 76 leading to the diaphragm upper chamber 58, and from the upper chamber 58 to the passage 76 leading from the hydraulic fluid injector 20. Again, the fluid connections or paths between the fluid inlet and outlet tubes 36, 38 and the respective injectors 18, 20 are also not visible in this view but are understandable with respect to Fig. 6.

Fig. 5 is a horizontal sectional view of the EETC valve 10 in Figs. 1 and 2, taken along line 5-5 in Fig. 2. This view shows more of the internal structure of the valve parts.

Fig. 6 shows diagrammatically the preferred embodiment of how the EETC valve 10 connects to a source of hydraulic fluid. In this embodiment of the invention, the source of hydraulic fluid is engine lubrication oil. In Fig. 6, a portion of oil pan 94 is cut away to show engine lubrication oil pump 90 and engine lubrication oil reservoir 92 in oil pan 94. As is well known in the art, outlet 96 of the oil pump 90 feeds oil to practically all of the engine moving parts under pump pressure through distributing headers (not shown). To provide a source of pressurized hydraulic fluid to the inlet fluid injector 18, the fluid inlet tube 36 is connected to the oil pump outlet 96. An optional replaceable filter 98 may be placed in the pressurized oil line to ensure that the oil flowing to the valve 10 does not clog the injectors. To provide a return path for the hydraulic fluid exiting from the outlet fluid injector 20, the fluid outlet tube 38 is connected to the oil reservoir 92 in the oil pan 94.

Figs. 7, 8, 13A, 13B and 15 show another preferred form of an EETC valve (designated with the numeral 100) which simultaneously controls the flow of TCF to plural parts of an engine. In one embodiment, the EETC valve 100 controls fluid flow to the radiator and the oil pan. This EETC valve is discussed in detail in U.S. Patent No. 5,458,096. (It should be noted that the present invention is applicable to
any embodiment of the EETC valve. For the sake of simplicity, reference will be made to EETC valve 10 and/or 100).

Fig. 14A diagrammatically shows one embodiment of the temperature control system according to the present invention in a GM 3800 V6 transverse internal combustion engine. The system includes a modified version of the multi-function EETC valve 100, with fluid paths to the intake manifold and the oil pan. The fluid flow paths to and from the automobile heater are not shown in this simplified diagram. The system shown in Fig. 14A functions as follows.

When the valve 100 is in the second position (i.e., open to TCF flowing to the radiator, closed to TCF flowing to the intake manifold/oil pan), the TCF enters a TCF jacket 200 formed in a cylinder block. From there, it is supplied to through passageways 202' to the cylinder head waterjacket 202. The TCF leaving the jackets 200 and 202 flows through the EETC valve 100 and is introduced to radiator 206 through radiator inlet passage 208. The TCF which enters the radiator 206 is cooled during its passage therethrough by air flow from cooling fan 210 located at the rear side of the radiator 206. The cooled TCF is supplied to a TCF pump 212 (e.g., a water pump) through the radiator outlet passage 214. The TCF supplied to the pump 212 is again circulated to the jackets 200 and 202.

Fig. 14B illustrates the temperature control system when the valve 100 is in the first position (i.e., closed to TCF flowing to the radiator, open to TCF flowing to the intake manifold/oil pan). In this embodiment, restrictors 400 are preferably utilized to restrict and/or prevent the flow of the TCF from the engine block jacket 200 to the cylinder head 202. Therefore, only a small amount of the TCF entering jacket 200 is supplied to the cylinder head jacket 202 (indicated in the figures by the small arrows). The smaller mass of TCF in the cylinder head will, accordingly, heat up quickly. Meanwhile the restricted mass of TCF in the block waterjacket 200 operates as an insulator to prevent heat loss. The TCF leaving the cylinder head jacket 202 is prevented from entering the radiator inlet passage 208 by EETC valve 100. Hence, the TCF bypasses the radiator 206 and enters the intake manifold jacket 204. From the intake manifold jacket 204, the TCF flows to the oil pan 94 through bypass passageway 216 and into heat exchanger 218. The heat exchanger 218 preferably comprises a U-
shaped heat conductive tube 220 which allows heat from the TCF to pass into the oil in the oil pan 94. Other tubing shapes are also suitable. The TCF exiting the heat exchanger 218 flows back into the pump 212 for recirculation into the engine block.

In cold temperature environments, or when an engine is first warmed up, the engine lubrication oil should be heated to its normal operating temperature as rapidly as possible, and maintained at that temperature. In prior art engine cooling systems, engine coolant is not employed to assist in this goal. To the contrary, prior art systems work against this goal by immediately circulating coolant through the jacket and removing heat from the engine block, and, thus, from the engine oil, inhibiting it from reaching its optimum temperature as quickly as possible.

The present invention helps to achieve that goal by circulating a portion of the TCF through the oil pan 94. Since the valve 100 is likely to be in the first position when the engine is in cold temperature environments, or when it is first warmed up, the oil in the oil pan 94 will receive warm or hot TCF when it needs it the most. The heat energy transferred from the warm or hot TCF into the oil allows the oil to more quickly reach its ideal operating temperature. In effect, the TCF diverted to the oil pan 94 recaptures some of the parasitic engine heat loss caused by circulation of the TCF.

The inventive system described herein allows the engine oil to capture some of the heat energy in the TCF after the engine is turned off. In contrast, the heat energy in the coolant of prior art cooling systems is wasted by being passed into the environment. Since the valve 100, in the present invention, will always be in the first position after engine cooldown, heat energy can pass by convection through the passageway 216 and into the oil pan 94. If the ambient air temperature is very cold, the valve 100 may even remain in the first position during and after engine operation. Thus, convective heating of the engine oil will continue after the engine is turned off. The mass of hot TCF has the potential to keep the engine oil warm longer after engine shut-off. As a result, the present invention provides substantial benefits in situations where an engine is subject to frequent on/off cycles, e.g., delivery vehicles.

As noted above, the EETC valve 100 may operate in alternate embodiments. For example, a second embodiment incorporates the EETC valve 100 to physically control fluid flow through the radiator. As a consequence of inhibiting
and permitting the flow to the radiator, the flow through the intake manifold and oil pan is controlled. This is diagrammatically shown in Figs. 14C and 14D and operates as follows. When the EETC valve 100 is in a first position, flow to the radiator is blocked and flow through the oil pan and through the intake manifold is permitted (e.g., engine warm-up phase). When the EETC valve 100 is in a second position (Fig. 14D), flow to the radiator is permitted. The flow to intake manifold and oil pan is not physically restricted, but the pressure from the water pump will cause a significant amount of the TCF to flow through the radiator with a minimal amount flowing through the intake manifold and the oil pan.

A third embodiment of the temperature control system is shown in Figs. 14E and 14F. A valve 300 controls the flow of fluid through the intake manifold jacket 204 which surrounds the intake manifold (not shown). For the purposes herein, the valve 300 can be any valve which is moved from a first position to a second position by hydraulic fluid pressure applied to a valve chamber, wherein the first position is associated with unrestricted fluid flow through an associated passageway and the second position is associated with either restricted or blocked flow through the passageway. One example of a valve 300 suitable for this purpose is described in Figs. 33-39 of this disclosure. However, the valve 300 can comprise any type of hydraulically fluid actuated valve such as a piston valve, diaphragm valve or the like. Furthermore, while the preferred valve is actuated by hydraulic pressure, other actuation mechanisms are well within the scope of this invention. The valve is shown positioned in close proximity to the EETC valve 100 for the sake of convenience. It should be well understood that the valve 300 may be placed at any suitable location for restricting and/or blocking flow into the intake manifold jacket 204.

It is also contemplated that the temperature control system can be configured such that the EETC valve 100 also controls flow of the temperature control fluid to the intake manifold. When it is desired to move the valve 100 into the second position, pressurized hydraulic fluid simultaneously flows along fluid outlet tube 174 and into the chamber (not shown) of the intake manifold flow control valve 300. The pressurized fluid in this chamber causes the valve 300 to move from the first position (unrestricted flow) to the second position (restricted or blocked flow).
When it is desired to move the valve 100 back into the first position, the hydraulic fluid flows from valve 300 back into the EETC valve 100 and out through the outlet hydraulic fluid injector. In this manner, the state of the EETC valve 100 determines the state of the valve 300.

The purpose of this control scheme is to reduce the amount of heat energy flowing through the intake manifold when the engine is hot. In a typical internal combustion engine, the intake manifold has an ideal temperature of about 120 degrees Fahrenheit (48.9 °C). In such engines, there is no significant advantage in heating the intake manifold to temperatures higher than about 130 degrees Fahrenheit (54.5 °C). In fact, extremely hot intake manifold temperatures reduce combustion efficiency. This is due to the fact that air expands as it is heated. Consequently, as the air volume expands, the number of oxygen molecules per unit volume decreases. Since combustion requires oxygen, reducing the amount of oxygen molecules in a given volume decreases combustion efficiency. Prior art cooling jackets typically deliver coolant through the intake manifold at all times. When an engine is running hot, the coolant temperature is typically in a range from about 220 to about 260 degrees Fahrenheit (104.4 °C - 126.7 °C). Thus, the coolant may be significantly hotter than the ideal temperature of the intake manifold. Nevertheless, the prior art cooling system will continue to deliver hot coolant through the intake manifold, thereby maintaining the intake manifold temperature in an excessively high range.

The second embodiment of the invention described herein employs the EETC valve 100 to restrict or block the flow of TCF through the intake manifold, thereby avoiding the unwanted condition described above. When the EETC valve 100 is in the first position, it is likely that the temperature of the TCF is below that which would cause the intake manifold to exceed its ideal operating temperature. Thus, when the EETC valve 100 is in the first position, flow of TCF through the intake manifold is permitted. This scheme functions with or without the modification to the temperature control fluid passageway for diverting the fluid to the oil pan.

The valve 300 may, instead, be mounted at the end of the intake manifold jacket 204 (not shown in the figures), thereby "dead heading" the flow of fluid through the jacket 204. "Dead heading" is used herein to describe the state whereby the flow
of fluid is blocked but the fluid still remains in the water jacket passage due to the continuous pumping of fluid by the engine's water pump. "Restricting" is used in this embodiment to describe the state whereby the flow of fluid is partially blocked but a portion of the fluid still flows in the water jacket passage due to the continuous pumping of fluid by the engine's water pump. Since heat energy is primarily transferred to and from the engine block by the flow of fluid, deadheading the flow will have almost the same effect as shutting off the flow. This is due, in part, to the cooling effect provided by the air passing through the intake manifold, which operates to extract the heat from the "stagnant" TCF in the water jacket of the intake manifold. A minimum amount of convective fluid heat flow will still occur between the intake manifold jacket 204 and the cylinder head and block jackets 200 and 202 in this configuration, since the channels between the cylinder head and the intake manifold are still open. However, it is more preferable to place the valve 300 in the passageway leading to the beginning of the intake manifold jacket 204 (shown in Figs. 14E and 14F), thereby preventing both fluid flow through the intake manifold jacket 204 and convective fluid heat flow between the jacket 204 and the jackets 200 and 202.

The configuration in Figs. 14A through 14F wherein the EETC valve 100 controls fluid flow to the radiator, oil pan and a portion of the engine block water jacket (e.g., the portion around the intake manifold) produces a highly effective engine temperature control system in a wide range of ambient temperature conditions, as well as during engine warm up. In cold temperature environments and during warm up, the EETC valve 100 allows flow of the TCF to the oil pan and the intake manifold, thereby causing the engine oil and intake manifold to more rapidly reach their ideal operating temperatures. Once the engine is sufficiently warmed up, or when the engine is operating in very hot ambient air temperatures, the EETC valve 100 shuts off flow of the TCF to both the oil pan and the intake manifold since neither the oil, nor the intake manifold need additional heat energy under either of those conditions.

The EETC valve 100 can also control the flow of the TCF to portions of the engine block water jacket other than the portion around the intake manifold. The valve 300 shown in Figs. 14E and 14F can, alternatively, be placed to block or restrict flow through portions of the cylinder block jacket 200 or the cylinder head jacket 202.
In another embodiment, a plurality of water jacket blocking/restricting valves can be simultaneously controlled from the hydraulic fluid system of the diaphragm valve 102. Figs. 14A through 14F show such additional valves 400 in phantom. Fig 14F illustrates the restricting/shutting off of some of the channels 202' between the engine block 200 and the cylinder head jacket 202.

The alternate embodiments shown in Figs. 14A through 14F illustrate the use of restrictor/shut-off valves to prevent or reduce the passage of fluid to a portion of the cylinder head and/or the intake manifold. As stated above, these configurations are beneficial when the engine is cold, such as during start-up, since they heat the oil to its optimum operating temperature as soon as possible. Although constant circulation of the TCF fluid through the engine, without including the radiator, will eventually heat up the engine oil, doing so will take considerably longer than desired. Accordingly, in these embodiments, the heat from the cylinder head and/or the intake manifold is channeled to the engine oil to heat it up directly. The EETC valve in these embodiments would, preferably, be similar to the valve depicted in Fig. 43. However, the flow would be directed to the intake manifold before proceeding to the oil pan.

The passageways controlled and the locations of the EETC and restrictor/shut-off valves will, of course, vary depending on the configuration of the engine chosen. Those skilled in the art, upon reading this disclosure, will be readily capable of varying the disclosed preferred embodiments without departing from the scope of the invention.

The EETC valve 100 can also be employed to address a design compromise inherent in prior art engine cooling systems employing prior art thermostats. Prior art Figs. 40 and 41 show a simplified diagrammatical representation of coolant circulation flow paths through such an engine. The coolant temperature is represented by stippling densities, hot coolant having the greatest density and cold coolant having the smallest density. Fig. 40 shows that when thermostat 1200 is closed, the coolant that exits water jacket 1202 flows through orifice 1204, into the intake side of water pump 1206, and then back to the water jacket 1202. Thus, the coolant circulates entirely within the engine water jacket 1202, avoiding radiator 1208. Fig. 41 shows that when
the thermostat 1200 is open, all of the coolant circulating through the radiator 1208, into the intake side of the water pump 1206, and then back to the water jacket 1202.

Fig. 41 is an idealized diagram of coolant flow. Since fluid takes the path of least resistance, most of the coolant will flow through the larger opening associated with the thermostat 1200, as opposed to the more restrictive orifice 1204. However, a small amount of coolant still passes through the orifice 1204 and into the intake side of the water pump 1206, as shown in prior art Fig. 42. Since this small amount of coolant is not cooled by the radiator 1208, it raises the overall temperature of the coolant reentering the water jacket to a level higher than is desired.

To minimize this problem, the opening associated with the thermostat 1200 is made as large as possible and the orifice 1204 is made as small as possible. However, if the orifice 1204 is made too small, circulation through the water jacket 1202 will be severely restricted when the thermostat 1200 is closed. This may potentially cause premature overheating of portions of the engine block and will reduce the amount of heat energy available for the heater and intake manifold during engine start-up and in cold temperature environments. If the orifice 1204 is made too large, the percentage of coolant flowing therethrough will be large when the thermostat 1200 is open. Accordingly, the average temperature of the coolant returning to the water jacket 1202 will be too hot to properly cool the engine.

Thus, prior art engine cooling systems must always attempt to strike the proper balance between extremes when sizing the orifice 1204, thereby resulting in a compromised, but never idealized, size. In an idealized system, the orifice 1204 is open and large when the thermostat 1200 is closed, and is closed when the thermostat 1200 is open.

Fig. 43 shows how the EETC valve 100 can be employed to create this idealized system. This embodiment is described in U.S. Patent No. 5,458,096.

The EETC valve 100 can also be employed in an anticipatory mode to address one problem in prior art engine cooling systems, specifically, the problem of sudden engine block temperature peaks caused when a turbocharger or supercharger is activated. These sudden peaks, in turn, may cause a rapid rise in coolant temperature and engine oil temperature to levels which exceed the ideal range. Since prior art
cooling systems typically cannot shut off flow of coolant to the intake manifold, the rise in engine block temperature causes even more unnecessary heat energy to flow around the already overheated intake manifold. Furthermore, if the engine is still warming up, the prior art wax pellet type thermostat might not even be open. The thermostat might also be closed even if the coolant temperature has reached the range in which it should open, due to hysteresis associated with melting of the wax.

The invention herein can employ the EETC valve 100 to lessen the temperature rise effects of the turbocharger or supercharger. When the turbocharger or supercharger is activated, a signal can be immediately delivered to the EETC valve 100 to cause it to move into its second position, if it is already not in that position. In the preferred system, this will stop the flow of TCF to the engine oil and through the intake manifold in anticipation of a rapid temperature rise in the oil and the intake manifold due to the action of the turbocharger or supercharger. Likewise, the flow of TCF through the radiator will lessen any peaking of the engine block temperature. A short time after the turbocharger or supercharger is deactivated, the EETC valve can then be returned to the state dictated by the ECU.

Figs. 9 through 12 disclose alternate embodiments of the EETC valve which utilize a piston for controlling flow. These embodiments are described in U.S. Patent No. 5,458,096.

Figs. 16A and 16B show one preferred hydraulic fluid injector 700 in cross-section which is suitable for controlling the state or position of the EETC valves in the invention. As noted above, the fluid injector 700 is solenoid activated and includes an electrical terminal 702 connected at one end to injector solenoid 704 and at the other end to an ECU (not shown). When the solenoid 704 is energized, it causes needle valve 706 to move up, thereby moving it away from seat 708 and opening orifice 710 to fluid flow. When the solenoid 704 is deenergized, biasing spring 712 causes the needle valve 706 to return to the closed position.

Fig. 16A shows the inlet fluid flow path from a source of pressurized hydraulic fluid, through the injector and to the valve chamber. The valve in this figure thus performs the function of the valve 18 in Fig. 4. Fig 16B shows the outlet fluid
flow path from the valve chamber, through the injector and to a reservoir of hydraulic fluid. The valve in this figure thus performs the function of the valve 20 in Fig. 4.

The fluid injector 700 is similar to a DEKA Type II bottom feed injector, commercially manufactured by Siemens Automotive, Newport News, VA. Although this injector is typically employed to inject metered quantities of gasoline into the combustion chamber of an engine, it can also function as a valve to pass other types of hydraulic fluid therethrough.

When the hydraulic fluid is engine lubrication oil, the Siemens type injector can be employed with only minor modifications such as an increased lift or stroke (e.g., .016 inches (0.004 mm), instead of .010 inches (0.0025 mm)) and a larger flow orifice 710 (e.g., .060" Ø area (0.015 mm)) for increased flow capacity. The biasing spring 712 is preferably a heavy armature spring to seal against up to 80 psi (551 kPa) pressure in a reverse position. The needle valve 706 preferably includes a 3% silicon iron armature 707 to obtain the appropriate lift. The metal housing of the injector is slightly modified and arranged to allow for twist snap-in assembly. The O-rings are smaller and relocated to be on the valve body. Also, since engine oil is not as corrosive as gasoline, internal components of the Siemens type injector do not need to be plated. Furthermore, the filter associated with commercially available injectors is not employed.

The inlet fluid injector 700 is preferably operated in a reverse flow pattern. That is, fluid flows through the inlet injector 700 in an opposite direction as the injector is normally employed in a gasoline engine. When the inlet injector 700 is operated in this manner, pressure from the valve chamber tends to seal the needle valve 706 against its seat 708, thereby lessening the tendency of the injector 700 to leak. This also ensures that the EETC valve remains open during engine off "hot soak" if conditions warrant an open state.

Fig. 16C shows an alternative type of hydraulic fluid injector 800 in cross-section which is suitable for controlling the state or position of the EETC valves in the invention. The injector 800 is similar to a DEKA Type I top feed injector, commercially manufactured by Siemens Automotive, Newport News, VA. In this type of injector, the hydraulic fluid flows through the entire length. Although Fig. 16C shows both fluid flow paths through the same injector 800, only one injector 800 is employed
for each path. The injector 800 is also preferably operated in a reverse flow pattern and without a filter. This type of injector has a numerous advantages over the DEKA Type II injector.

When employing the injector 800 in an EETC valve, the top of the injector 800 is connected directly to the EETC valve's upper chamber, not to a common passage. This allows for more versatile packaging configurations because the inlet and outlet injectors do not need to be physically near each other. It also reduces the amount of retained trapped air in the EETC valve, potentially eliminating the need to bleed out trapped air when filling the chamber. The injector 800 is also smaller and cheaper than the injector 700. One disadvantage of this type of injector is that it is more difficult to get hydraulic fluid such as oil to flow smoothly therethrough.

Fig. 17 shows a block diagram circuit of the connections to and from ECU 900 for controlling the state or position of the EETC valves. The preferred embodiment of the ECU 900 receives sensor output signals from at least the following sources:

1. an ambient air sensor in an air cleaner (clean side) or other suitable location;

2. a temperature sensor at the end of the engine block's (or the inlet to the cylinder head) temperature control fluid water jacket;

3. a pressure sensor in the engine block's temperature control fluid water jacket;

4. a temperature sensor for providing a temperature indicative of the engine block or engine oil temperature;

5. a pressure sensor in the engine block oil line; and

6. a pressure sensor in the EETC valve's hydraulic fluid passageway.

The ECU 900 utilizes some or all of those sensor signals to generate open/close command signals for the fluid injectors of the EETC valve. As noted above, the hydraulic fluid pressure signals are also employed to detect unsafe operating conditions. The engine oil fluid pressure signal can be employed to detect unsafe
operating conditions and/or to determine when the oil lubrication system is sufficiently pressurized to allow for proper operation of the EETC valve.

A typical control routine for opening a diaphragm type EETC valve sized to replace a prior art wax pellet or bimetallic coil type thermostat and employing fluid injectors connected to the engine lubrication oil system is as follows:

1. If engine is being started, wait appropriate amount of time until engine oil is adequately pressurized. It will typically take two to three seconds to allow it to reach a minimum pressure of 40 psi (275.8 kPa).

2. Activate solenoid of inlet fluid injector to open its valve. (Close valve of outlet fluid injector, if it is not already closed.)

3. Wait until chamber pressure (as measured by the fluid pressure sensor) reaches about 25 psi (172.3 kPa).

4. Activate a two second timer in the ECU.

5. After two seconds, deactivate the solenoid of the inlet fluid injector to close its valve.

6. If the fluid pressure sensor detects a pressure drop below 25 psi, repeat steps 2-5.

If the engine oil is warm, the total time to complete steps 2-5 will be about six seconds. If the engine oil is cold, step 2 will take longer, thereby lengthening the total time.

The ECU 900 can also perform other emergency control functions to maintain the TCF in a safe range. For example, in extremely hot ambient air conditions, the temperature of the TCF might exceed a safe range, even if the EETC valve is fully open. In typical prior art vehicles, an overheating condition will be signalled to the driver through a dashboard mounted engine warning light or the like. The novel system shown in Fig. 17 can respond to this condition by temporarily opening the heater core valve and/or shutting off the vehicle’s air conditioning system. The first of these measures will assist in removing excess heat from the engine block. The second of these measures will reduce the load on the engine, thereby reducing its heat energy output. If these measures still fail to reduce the temperature of the TCF to a safe range, the system can then activate the engine warning light. Another dashboard mounted light
can indicate when the ECU has taken emergency control of the vehicle’s climate control system.

Likewise, in extremely cold, sub-zero ambient air temperatures, the heater core valve can be automatically deactivated or restricted to avoid draining heat energy from the engine block until the temperature of the TCF reaches an acceptable minimum level.

One example of how the ECU 900 controls the state or position of an EETC valve based on specific parameters is described in Figs. 19-21 of this disclosure, and will be discussed in more detail hereinbelow.

Fig. 18 diagrammatically shows the flow path of the TCF through a heat exchanger in the oil pan from the passageway 160. The passageway 160 can also lead to other passages and tubes disposed in other engine parts, thereby allowing the TCF to warm or heat those other parts too. For example, additional TCF passages can lead to tubes disposed in the reservoir of the automatic transmission, the brake system’s master cylinder or ABS system, windshield washer fluid or the like. The TCF would then flow to these parts whenever it flows to the oil pan. Alternatively, flow to one or more of these parts can be controlled by a separate flow control valve so that when the TCF flows to the oil pan, the fluid selectively flows to desired parts in accordance with different temperature parameters.

The EETC valves described herein are designed to replace the prior art wax pellet type or bimetallic coil type thermostat. These thermostats are typically located in an opening connecting a radiator inlet passage to an outlet of an engine water jacket. Accordingly, the EETC valves are dimensioned to fit into that opening. Likewise, the EETC valve housing includes holes to allow the valves to be mounted in that opening in the same manner as the prior art thermostats are mounted within the engine. Thus, the EETC valves can be retrofitted into existing engine TCF passageways. The only additional apparatus required to install the EETC valve are the hydraulic fluid lines and electrical wires for connection to the inlet and outlet hydraulic fluid injectors. These lines and wires can be placed inside the engine compartment wherever space permits.

It may be desirable to modify the TCF passageway to provide the extra passageways 160 and/or 216 shown diagrammatically in Figs. 14A through 14F and Fig. 18.
Likewise, if the EETC valve is employed to control the intake manifold flow control valve 300 and/or the cylinder head valve 400, the fluid outlet tube 174 must be provided from the EETC valve to the valve 300.

Notwithstanding the above discussion of the valve location, the EETC valve can alternatively be located wherever it can properly perform the function(s) attributed thereto. Likewise, the EETC valve can have other sizes which are appropriate for its alternative location.

The EETC valves are suitable for any form of internal combustion engine which opens and closes an engine block TCF passageway to a radiator. Thus, both gasoline and diesel engine environments are within the scope of the invention.

Although the hydraulic fluid which controls the state or position of the EETC valve is preferably engine oil, it can be any type of pressurized hydraulic fluid associated with a vehicle powered by an internal combustion engine. In one alternative embodiment, the hydraulic fluid is power steering fluid wherein the source of the pressurized hydraulic fluid is the high pressure line of a power steering pump. The hydraulic fluid emptied from the EETC valve flows into the power steering fluid reservoir. In this embodiment, the power steering pump is modified so that it provides high pressure at all times. That is, high pressure can be tapped from the pump when the wheel is not being turned and when the engine is off, in addition to when the wheel is being turned. Also, this version employs a prior art pressure regulating valve in the high pressure line to achieve a constant output pressure of about 10 to about 120 psi (69 kPa - 83 kPa), regardless of the varying input pressure of the power steering unit, which can range up to 1000 psi (6894 kPa). In this manner, the EETC valve is never exposed to pressures exceeding about 120 psi (827 kPa), regardless of the output pressure of the power steering unit.

The invention also contemplates the use of alternate means for controlling the EETC valve, although these may not be preferred. For example, TCF fluid could be fed to a separate pump which pressurizes the fluid. The pressurized TCF is then fed into the injectors for actuating the diaphragm. In yet another embodiment of the invention, an electro-mechanical servo could actuate the valve. Those skilled in the art
would readily appreciate the variations that are possible within the scope of this invention.

Dead heading or restricting TCF flow through portions of the water jacket reduces heat loss from the engine block. It also reduces the mass of TCF circulating through the water jacket, thereby raising the temperature of the circulating mass above what it would be if the mass was larger. Both of these effects allows the engine block to warm up more quickly. As noted above, heat energy is primarily transferred to and from the engine block by the flow of fluid. Therefore, dead heading or restricting the flow will have almost the same effect as shutting off the flow. Since dead heading or restricting TCF flow effectively traps all or part of the TCF in the dead headed or restricted passageway, the trapped TCF acts as an insulator. That is, the hot fluid in the water jacket prevents the engine heat from readily dissipating to the environment. This is due, primarily, to the fact that the TCF is a better insulator than a conductor. Accordingly, this insulating function further reduces heat loss from the engine block.

Some preferred materials for constructing the EETC valve and operating parameters are described in U.S. Patent 5,458,096.

The ECU 900 can be programmed with specific information to control the state of the EETC valves and any restrictor/shutoff valves 300 and/or 400 associated therewith.

Figs. 19 and 20 show one example of how the ECU 900 is programmed with information to control the state of an EETC valve based upon the temperature of the TCF and the ambient air temperature, whereas Fig. 21 shows the state of prior art wax pellet type or bimetallic coil type thermostats within the same ranges of temperatures.

Turning first to Fig. 21, prior art wax pellet type or bimetallic coil type thermostats are factory set to open and close at a preselected coolant temperature. Thus, the state of these thermostats are not affected by the ambient air temperature. That is, no matter how cold the ambient air temperature becomes, these thermostats will open when the coolant temperature reaches the factory set value. A thermostat designed for use in a cooling system employing a permanent type antifreeze (as opposed to an alcohol
type antifreeze) is typically calibrated to open at about 188 to about 195 degrees Fahrenheit (86.7 °C - 90.6 °C) and be fully open between about 210 to about 212 degrees Fahrenheit (98.9 °C - 100 °C).

Since the EETC valves in the invention are computer controlled, their states can be set to optimize engine temperature conditions over a wide range of ambient air temperatures and TCF temperatures. In one embodiment, the ECU 900 in Fig. 17 is programmed with the curve shown in Fig. 19. The curve is defined by a two-dimensional mathematical function of \( t_1 = f(t_2) \), where \( t_1 \) is the temperature of the TCF in the engine block and \( t_2 \) is the ambient air temperature, \( t_1 \) and \( t_2 \) being axes on an orthogonal coordinate system (i.e., defined by a set of predetermined values having a TCF component and an ambient air component.) The curve divides the coordinate system into two regions, one on either side of the curve.

In operation, the ECU 900 continuously monitors the ambient air temperature and the TCF temperature to determine what state the EETC valve should be in. If coordinate pairs of these values lie in region 1 of the Fig. 19 graph, the EETC valve is closed (or remains closed if it is already in that state). Likewise, if coordinate pairs of these values lie in region 2, the EETC valve is opened (or remains open if it is already in that state). If coordinate pairs lie exactly on the curve, the ECU is programmed to either automatically select one of the two regions or to modify one or both of the values so that the coordinate pair does not lie exactly on the curve.

Alternately, the state of the EETC valve could be controlled simply based on the actual engine oil temperature. In such an embodiment, the actual engine oil temperature would be compared to a predetermined optimum engine temperature which is preferably a function of the ambient temperature, as shown in Figure 25 (i.e., a curve defined by a set of predetermined values having an ambient air temperature component and an engine oil temperature component.) When the actual engine oil temperature is colder than the desired/optimum temperature, the EETC valve could be closed thereby raising the engine temperature. Similarly, if the actual engine oil temperature is higher than the desired/optimum temperature, the EETC valve could be opened, thereby circulating the TCF through the radiator to cool it down. One deficiency with using the engine oil temperature as a controlling factor is the lag time involved in bringing
the oil to a prescribed temperature. Additionally, there are upper and lower temperature limits on the TCF that should not be exceeded in current automobile cooling systems.

The curve shown in Fig. 19 has been experimentally determined to provide optimum engine temperature control in a typical internal combustion engine when an EETC valve replaces the typical prior art thermostats described above. As shown, at least a portion of the curve has a non-zero slope. However, the curve can be different, depending upon the desired operating parameters of the engine and its accessories. An engine employing an EETC valve which is controlled according to the curve in Fig. 19 will have lower emissions, better fuel economy and a more responsive vehicle climate control system than the same engine employing the thermostat. These improvements will be greatest in the lower ambient temperature ranges.

To illustrate some advantages of the EETC system, consider a vehicle which is first started up when the ambient air temperature is zero degrees Fahrenheit (-17.8 °C). Until the coolant or TCF temperature reaches about 188 degrees Fahrenheit (86.7 °C), the prior art system in Fig. 21 and the EETC system in Fig. 19 will both prevent the coolant or TCF from flowing through the radiator. However, when the coolant temperature exceeds about 188 degrees Fahrenheit (86.7 °C), the prior art system will open the thermostat and allow either some or virtually all of the coolant to flow through the radiator, thereby lowering the coolant temperature. This reduces the ability of the vehicle's heater/defroster to deliver hot air (i.e., heat) to the vehicle interior and windows because the coolant flowing through the heater core will be cooler than if it did not flow through the radiator. Furthermore, this also unnecessarily removes valuable heat energy from the engine block.

When the ambient temperature is zero degrees Fahrenheit (-17.8 °C), typical internal combustion engines often do not need to be cooled by coolant flow through the water jacket since the ambient air presents a significant heat sink. Furthermore, when the ambient air temperature is about zero degrees Fahrenheit (-17.8 °C), the heat energy emitted by engine combustion often does not raise the oil temperature or the engine block above the level desired for safe and optimum operation.

In fact, in sub-zero ambient air temperatures, the engine block of a typical internal combustion engine will have an average temperature of less than 150 degrees Fahrenheit.
(65.6 °C) which is less than the ideal operating temperature. Accordingly, high oil viscosity and sludge build-up, which increases emissions and lowers fuel economy, are virtually unavoidable conditions when operating engines having prior art thermostat controlled cooling systems in sub-zero ambient air temperatures.

Consider the same vehicle operating in the same ambient temperature environment with an EETC valve system. As shown in Fig. 19, the EETC valve will remain closed until the TCF exceeds about 260 degrees Fahrenheit (126.7 °C), a condition that might not even occur unless the engine is driven very hard and/or fast. Consequently, the TCF flowing through the engine water jacket will not unnecessarily remove valuable heat energy from the engine block and engine lubrication oil. Furthermore, the TCF flowing through the heater core will become hot more quickly and will remain hotter than the coolant in the Fig. 21 scenario, thereby resulting in improved defrosting and vehicle interior heating capabilities.

In a control system employing the curve in Fig. 19, the EETC valve can be any of the valves described in the invention. If the EETC valve is employed in conjunction with one or more of the restrictor/shutoff flow control valves 300 or 400, the curve can be slightly modified to obtain optimum temperature control conditions. Specifically, the portion of the curve between about 58 to about 80 degrees Fahrenheit (about 14.4 °C to about 26.7 °C) in Fig. 19 can have the same slope as the portion of the curve between about 60 degrees to about zero degrees Fahrenheit (about 15.6 °C to about -17.8°C), as shown in Figure 20.

When the EETC valve is employed in conjunction with the additional flow control valves, emission levels will even be lower, fuel economy even greater, and the vehicle climate control system even more responsive than the system employing only the EETC valve. If the EETC valve 100 is employed in the system, hot TCF will flow through the oil pan at virtually all times when the ambient air temperature is zero degrees Fahrenheit (-17.8 °C). This will improve the oil viscosity and reduce engine sludge build-up.

When the EETC valve is employed in conjunction with the intake manifold flow control valve 300, engine performance improvements will occur in high
temperature environments as a result of avoiding excessive heating of the intake manifold, as discussed above with respect to the system in Figs. 14A through 14C.

When the EETC valve is employed in conjunction with flow control valves associated with the cylinder head and/or cylinder block, as discussed above with respect to Figures 14A through 14C, very precise tailoring of engine temperature can be achieved. For example, when the ambient temperature is very low and the EETC valve is closed, the one or more flow control valves are likewise closed to restrict and/or dead head the TCF that would ordinarily flow through certain portions of the engine block. Preferably, the TCF is allowed to flow only through the hottest portions of the engine block, such as areas of the cylinder head jacket closest to the cylinders. This achieves at least two desired effects. First, the TCF flowing through the limited portions of the engine water jacket will not unnecessarily remove valuable heat energy from the engine block and engine lubrication oil. Second, the limited amount of the TCF which exits the water jacket will be hotter than if the TCF flowed through all parts of the engine block. Thus, the TCF flowing through the heater core will become hot more quickly and will remain hotter than if the TCF flowed through all parts of the engine block, thereby resulting in improved defrosting and vehicle interior heating capabilities.

Fig. 22A shows a valve state graph which employs a curve similar to the curve in Fig. 20 but which employs the valve states to control the state of the EETC valve and two restrictor/shutoff valves. In region 1, the EETC valve is closed and the restrictor/shutoff valves are in an restricted/blocked state. In region 2, the EETC valve is open and the restrictor/shutoff valves are in an unrestricted/unblocked state.

Fig. 23 graphically shows a dotted curve of the actual temperature of the temperature control fluid measured in an engine block of a GM 3800 transverse engine equipped with an EETC valve and two restrictor/shutoff valves when the state of the valves are controlled according to the Fig. 22A scheme. The restrictor/shutoff valves are located on either side of a V-shaped engine block in the outer TCF flow passages around the cylinder liner, and together restrict the flow through the engine block by about 50 percent in their fully restricted state. Fig. 23 also shows a dashed curve of the actual temperature of engine coolant measured in the engine block when a prior
art wax pellet type or bimetallic coil type thermostat is employed and its state determined according to the prior art Fig. 21 scheme.

The prior art thermostat operates to try to maintain a constant coolant temperature in a range from about 180 to about 190 degrees Fahrenheit (about 82.2 °C to about 87.8 °C). However, when the ambient air temperature is very hot (e.g., 100 degrees Fahrenheit (37.8 °C)), the coolant temperature will exceed the desired range even if the thermostat is fully open and if the engine is running under continuous high load conditions. This is because the ability of the vehicle's cooling system to cool the coolant is dependent upon the capacity of the radiator. It is usually impractical and too expensive to install a radiator large enough to maintain temperatures below 200 degrees Fahrenheit (93.3 °C) at all times. Thus, regardless of the type of flow control valves employed in the vehicle's engine, coolant temperatures will exceed the optimal range in hot weather conditions.

In very cold ambient temperatures such as sub-zero temperatures, the coolant temperature in the prior art system will be below the desired range and will continue to decrease with decreasing ambient air temperatures. This will cause a significant decrease in fuel economy and a significant increase in exhaust emissions for all of the reasons discussed above. Sludge formation will also be a significant problem.

The system employing the EETC valve and restrictor/shutoff valves shows an improved TCF temperature curve because it maintains the TCF temperature more closely to the optimum range throughout a greater ambient temperature range. When the ambient air temperature is very hot (e.g., 100 degrees Fahrenheit (37.8 °C)) and full flow through the radiator has begun, the TCF temperature will be slightly less than the coolant temperature in the prior art system, mainly as a result of the greater flow allowed through the EETC valve, as compared to the prior art wax pellet type thermostat. However, the cooling capability of the system in the invention will still be limited by the fixed capacity of the radiator.

In cold ambient air temperatures, especially sub-zero temperatures, the system in the invention maintains the TCF temperature at values significantly higher than the coolant temperature in the prior art system. This is because the restrictor/shutoff valves have been placed in the state where they restrict or shut off a
portion of flow through the engine block. This flow restriction reduces the heat energy loss from the engine block, thereby allowing the limited amount of flowing TCF to reach a greater temperature. The engine block heat energy loss is reduced in at least two ways. First, less mass of TCF flows through the water jacket so less heat energy is transferred to the TCF where it is lost to the atmosphere. Second, the restricted and/or trapped TCF acts as an insulator around portions of the engine block. Since the limited amount of flowing TCF is at a greater temperature than the prior art coolant, the TCF improves the operating capability of the vehicle interior heater and defroster. Furthermore, since the engine operates at a hotter temperature, engine out exhaust emissions are lower, fuel economy is greater than in the prior art system. Also, sludge is less likely to form in the engine.

Instead of controlling the state of the EETC valve and restrictor/shutoff valves in accordance with the curve shown in Fig. 22A, the EETC valve and restrictor/shutoff valves can be controlled according to separate curves, as shown in Fig. 22B. By employing separate curves, the flow of TCF can be more precisely tailored to achieve a more optimum actual TCF temperature in Fig. 23. At very high ambient air temperatures, the EETC valve should normally be fully open and the restrictor/shutoff valves should normally be fully unrestricted/unblocked. At very low ambient air temperatures, the EETC valve should normally be fully closed and the restrictor/shutoff valves should normally be fully restricted/block blocked. However, it may be more desirable for ideal engine operating conditions to keep one or both of the restrictor/shutoff valves open in mid-temperature ranges, even after the EETC valve has closed. Fig. 22B shows a region 3 wherein these dual states are achieved. In one embodiment of the invention, a TCF temperature differential of about 15 degrees (8.3 °C) is employed.

A system employing the curves shown in Fig. 22B will allow the restrictor/shutoff valve(s) to open or unblock the TCF passageway shortly before the EETC valve opens flow to the radiator at a given ambient air temperature. One advantage of this system is that the temperature of the TCF circulating through the engine block’s water jacket will become more homogeneous by opening the restrictor/shutoff valves before the EETC valve is opened, thereby improving the overall accuracy of the system in determining when to open the EETC valve. This is because the total TCF
mass will be heated to the desired programmed temperature (as determined by the EETC valve curve) before TCF flow is introduced to the radiator. Time delays can be incorporated to prevent the EETC and/or restrictor valve from oscillating between open and closed positions. Alternately, additional curves could be utilized as will be discussed below.

When the restrictor/shutoff valves are in their restricted or blocked position, the temperature TCF in different portions of the engine block can vary significantly. For example, if the fluid in the outer water jacket passageways is dead headed, it will be colder than the fluid in the inner water jacket passageways. When the restrictor/shutoff valves are opened, the hotter and colder fluids immediately begin to mix, thereby reducing the variation in temperature of the TCF in different portions of the water jacket. Thus, as the TCF continues to heat up, the measured TCF temperature, which determines when to open the EETC valve, will be more accurate.

Some engines, like the GM 3800 V-6 engine, utilize a random pattern of openings to connect the waterjackets between the engine block and the cylinder head. Accordingly, the restrictor/shutoff flow control valves must be properly located so as to restrict or block the continuous flow path between the block and the cylinder head so as to maintain a mass of TCF in the block for faster warm up. Alternately, the engine waterjackets themselves could be designed to operate with the EETC valve to provide additional efficiency. An example of such an embodiment is illustrated in Figures 44A and 44B, and designated generally as 1400, wherein two individual waterjacket flow paths are incorporated into the engine, 1402 and 1404, respectively. The waterjackets are schematically shown external to the associated engine components for sake of clarity. However, it should be understood that the waterjackets are, preferably, integral with the engine components. One flow path 1402 would be the normal waterjacket path from the water pump 1406 through the engine block 1408 into the cylinder head 1410 and intake manifold 1412. The second waterjacket 1404 would flow from the water pump 1406 directly to the cylinder head 1410, intake manifold 1412, heater/defroster circuit (not shown), and engine oil pan 1414, by-passing the engine block 1408. An EETC valve as described hereinabove or, alternately, a rotary valve 1416 would be incorporated to direct the TCF between the two waterjackets depending on the operational state of
the engine. Fig. 44A illustrates the novel system during engine warm-up. The EETC valve 100 is in its closed position, inhibiting TCF flow to the radiator. Hence, substantially all the TCF is directed to the intake manifold and the oil pan 1414 where it exchanges heat with the oil. The TCF is then directed through the water pump 1406 to a second control valve 1416. Control valve 1416, during warm-up, is in a state wherein preferably all the TCF is directed along the by-pass waterjacket 1404 into the cylinder head 1410 and intake manifold. Waterjacket 1402 is, effectively, blocked, thereby trapping a mass of TCF within the engine block. The TCF flowing through the by-pass waterjacket 1404 into the cylinder head will quickly increase in temperature since there is less mass being exposed to the heat of the cylinder heads. Meanwhile, the TCF trapped in the engine block 1408 will function as an insulator, preventing unneeded heat loss and, consequently, resulting in lower exhaust emissions, better fuel economy and quicker heater/defroster capabilities. Restrictor valves may be incorporated between the cylinder head 1410 and the intake manifold 1412 (similar to Figs. 14E and 14F). These valves may be actuated to prevent or reduce TCF flow therethrough when the TCF reaches a predetermined temperature which may have an adverse effect on the combustion of the fuel, as described above. Alternately, and more preferably, the EETC valve 100 controls the TCF flow into the intake manifold, as well as, the oil pan.

Restrictor valves (not shown) may also be incorporated between the engine block 1408 and the cylinder head 1410 to inhibit the flow of TCF between the two during warm-up. However, the continuous flow of the TCF through the by-pass water jacket 1404 will obstruct the passage of TCF from engine block 1408 to the cylinder head 1410. Accordingly, depending on the design of the waterjacket, restrictor valves may not be required.

The last portion of the Background of the Invention describes that the prior art technique of controlling internal engine temperature solely by controlling engine coolant temperature is crude and inaccurate. The Background of the Invention also describes how this technique often causes overheating or overcooling of the engine, even when the coolant temperature is maintained at a predesired level. The invention described in Figs. 19-23 significantly reduces the amount of engine overheating and overcooling.
To even more accurately control the internal engine temperature, the invention described in Figs. 19-23 may be modified to employ two or more different curves for controlling the state of the EETC valve and the restrictor/shutoff valves. The appropriate curve is selected by comparing the actual engine oil temperature to a preselected engine oil temperature value. In the preferred embodiment of the invention, the preselected value is a temperature associated with optimum internal engine performance (e.g., the temperature which maximizes fuel economy and minimizes engine out exhaust emissions). In one embodiment of the invention, this value may be fixed. However, in the preferred embodiment of the invention, this value is related to the current ambient air temperature.

Selecting between different curves further improves the performance of the engine temperature control system because the state of the EETC valve and restrictor/shutoff valves becomes more responsive to the actual internal engine temperature (as measured by engine oil temperature) rather than when only a single curve is employed for controlling each of the valves.

Fig. 24 is generally similar to Fig. 20, except that Fig. 24 shows three EETC valve curves, a solid line "Normal Curve", a dotted "High Load Curve", and an Xed line "Extreme High Load Curve." The "Normal Curve" is generally similar to the curve shown in Fig. 20. However, the curves in Fig. 24 are based upon empirical data for the GM 3800 transverse engine. Thus, the "Normal Curve" in Fig. 24 differs slightly from the curve shown in Fig. 20, which is not necessarily optimized for that engine. To simplify the explanation of the multiple curve embodiments, the valve states and regions are not labelled in the multiple curve figures.) The state of the EETC valve is controlled in accordance with the "Normal Curve" whenever the actual engine oil temperature is at or below a preselected engine oil temperature. The state of the EETC valve is controlled in accordance with the heavy load or "High Load Curve" whenever the actual engine oil temperature exceeds the preselected engine oil temperature. The state of the EETC valve is controlled in accordance with the "Extreme High Load Curve" whenever there is a frequent rate of shifting between the "Normal Curve" and the "High Load Curve." Such frequent shifting indicates that the EETC valve is closing too often to maintain the desired engine oil temperature, as further explained below.
The "Normal Curve" will typically be employed when the vehicle is driven under light load conditions. This will occur approximately 80% of the time. The "High Load Curve" will typically be employed during the remaining time. Heavy load conditions may occur when a vehicle is driven at high speed, when the vehicle is fully loaded or pulling a trailer, or while climbing a mountain in hot ambient air temperatures.

The "High Load Curve" may have the same overall general appearance as the "Normal Curve," except that the "High Load Curve" is shifted down from the "Normal Curve" by about 50 degrees Fahrenheit (27.8 °C). Likewise, the "Extreme High Load Curve" may have the same overall general appearance as the "High Load Curve," except that the "Extreme High Load Curve" is shifted down from the "High Load Curve" by about 20 degrees Fahrenheit (11.1 °C).

The preselected engine oil temperature is a value associated with the preferred operating temperature of the engine. Each engine has an optimum operating temperature for maximizing performance (i.e., horsepower output), maximizing fuel economy and minimizing engine out exhaust emissions. The optimum operating temperature may be different for each of these parameters, although the optimum temperature for maximizing fuel economy tends to be similar to that for minimizing emissions. The examples described herein focus primarily on fuel economy and emissions, not engine performance. Thus, the preselected value described herein is one which optimizes internal engine performance as defined by fuel economy and engine out exhaust emissions. However, at low temperatures, a system with the EETC valve and restrictors should also generate increased engine horsepower.

In one embodiment of the invention, this value is fixed. That is, a single optimum engine oil temperature is selected which results in the greatest fuel economy and the lowest engine out exhaust emissions for the most frequently encountered ambient air temperature. In this embodiment, the actual engine oil temperature (as measured in the oil pan) is compared to the preselected optimum value. The result of the comparison is employed to select the appropriate curve, as described above.

In the preferred embodiment of the invention, the preselected value is not fixed. Instead, it is dependent upon the current ambient air temperature. The
Background of the Invention explains that as the ambient air temperature declines, the internal engine components lose heat more rapidly to the environment. Also, there is an increased cooling effect on the internal engine components from induction air. To counter these effects and thus maintain the internal engine components at the optimum operating temperature, the engine oil should be hotter in cold ambient air temperatures than in hot ambient air temperatures. The optimum engine oil temperature can be plotted against the ambient air temperature based on empirical data and known engine specifications. To determine the preselected optimum value for use in the comparison, the current ambient air temperature is measured and the optimum engine oil temperature is selected based on the value indicated on the plot.

Fig. 25 shows one such empirically determined plot for a GM 3800 transverse engine. The plot shows that the optimum engine oil temperature increases as the ambient air temperature decreases. The plot in Fig. 25 may be shifted upwards or downwards when the vehicle is operating in high or low altitudes. Empirical testing of each engine in high and low altitude conditions is required to determine whether the plot will be shifted upwards or downwards. Of course, the plot will be slightly different if a specific parameter is more important (e.g., fuel economy, engine out exhaust emissions, engine performance). Hence, it is possible to vary the curve shown in Figure 25 during a typical engine operation. For example, the ECU could receive signals indicating that a large sudden increase in acceleration has been commanded, e.g., significant depression of gas pedal on entering a highway. Accordingly, the curve could be altered or changed to a curve which provides higher performance with less emphasis on fuel economy. Those skilled in the art would readily appreciate the variations to the system that could be practiced within the scope of this invention.

As noted in the Background of the Invention, engine coolant temperature rises more rapidly than the internal engine temperature during engine start-up or warm-up. Since the prior art thermostat is actuated by coolant temperature, it often opens before the internal engine temperature has reached its optimum value, thereby causing coolant in the water jacket to prematurely cool the engine. As described above, exhaust emissions from cold running engines are a major source of air pollution. For example, a delivery truck or taxi operating in a city environment during the cold weather season
ordinarily covers short distances at slow speed and makes frequent stops. Accordingly, the engine seldom gets hot enough to drive the water and vapor out of the crankcase resulting in the formation of sludge. In order to prevent the sludge from forming in the oil it is desirable to maintain the engine oil at an elevated temperature. However, prior art thermostats are set to open at about 195 degrees Fahrenheit (90.6 °C) which, during start-up, corresponds to an engine oil temperature which is considerably below the desirable temperature for preventing sludge. Furthermore, opening the thermostat and permitting low temperature coolant to flow into the engine block slows the heating of the oil. This results in a "slowing" effect in obtaining the optimum engine oil temperature value.

By employing the novel EETC valve and a special curve during engine start-up, the optimum engine oil temperature value is reached sooner than with a prior art thermostatic system. As a result, the engine oil operates at or near its optimum temperature value for a longer period of time during engine operation. Moreover, the maintenance of engine oil at a higher temperature for a longer period of engine operation, almost entirely prevents the formation of sludge in the crankcase and oil pan. The quicker heat-up of the oil also provides improved engine out exhaust emissions during warm-up and in cold environments thereby providing significant environmental benefits. As an added benefit, the quicker heat-up of the engine greatly improves the vehicle heater/defroster responsiveness and effectiveness. An engine operating at or near optimum temperature will also have better fuel economy when compared with a cold running engine. Hence, the EETC and restrictor valves, in combination with the operational curves, provide an optimum system for controlling engine performance. Whenever the engine is started, no heat will escape through the radiator until the TCF temperature reaches its maximum operational level (e.g., approximately 240°F to 250°F range (115.6°C to 121.1°C)) and remains at that temperature level until the engine oil, preferably as measured in the oil pan, reaches and sustains its optimum running temperature.

Fig. 26 shows two EETC valve curves, a "Normal Curve" similar to that shown in Fig. 24, and a "Start-Up/Warm-Up Curve." The "Start-Up/Warm-Up Curve" is generally similar to the "Normal Curve," except that the "Start-Up/Warm-Up
Curve" has a "bump-up" region from about 110 degrees Fahrenheit to about 20 degrees Fahrenheit (about 43.3 °C to about -6.7 °C). The bump-up region has a maximum bump-up of about 100 degrees Fahrenheit (36.1 °C) when the ambient air temperature is about 85 degrees Fahrenheit (29.4 °C). The bump-up becomes smaller as the ambient air temperature approaches about 20 degrees Fahrenheit (-6.7 °C). The maximum bump-up is about 50 degrees Fahrenheit (27.8 °C) compared to the prior art thermostat.

During engine start-up or warm-up, the engine oil will almost always be colder than the optimum temperature. Thus, in most situations, the "Start-Up/Warm-Up Curve" will be employed during initial vehicle operation. Once the engine oil reaches its optimum temperature, as determined by Fig. 25, the system switches to the "Normal Curve." In rare instances, the initial engine oil temperature will be at or greater than the optimum temperature during engine start-up. This may occur if the engine is only shut off for a few seconds, or if the engine is started shortly after a period of heavy loading. In these instances, the EETC valve is operated according to the "Normal Curve", instead of the "Start-Up/Warm-Up Curve".

The inventions illustrated in Figs. 24 and 26 are preferably employed in the same system. Thus, the EETC valve actually follows at least three curves during vehicle operation, one curve during warm-up/start-up, one curve during normal operation subsequent to warm-up/start-up, and one curve during high load conditions subsequent to warm-up/start-up. A fourth curve for extreme high load conditions may be included, if desired.

Although Figs. 24 and 26 illustrate the operation of an EETC valve, the restrictor/shutoff valves may also be controlled in a similar manner. Preferably, the restrictor/shutoff valves follow their own curves, as shown in Fig. 22B. These curves are shifted down versions of the EETC valve curve. If this feature was shown in Fig. 24, there would be a total of four curves. The extra curve would represent the normal curve for the restrictor/shutoff valves. (There will be no high load curve for the restrictor/shutoff valves because in a high load condition, the restrictor/shutoff valves should be fully retracted.) Fig. 26 would show a total of four curves (excluding the prior art curve). The two extra curves in that figure would represent the normal curve
and the start-up/warm-up curve for the restrictor/shutoff valves. For simplicity, this feature is merely described, but not illustrated.

Fig. 27 is a flowchart of the system for employing the start-up/warm-up curve, normal curve and high load curve of Figs. 24 and 26. The steps in the flowchart are fully explained in the discussion above.

Fig. 28 shows a block diagram circuit of the connections to and from ECU 900 for controlling the state or position of the EETC valve. Fig. 28 is generally similar to Fig. 17, except that the ECU 900 in Fig. 28 processes the received sensor output signals according to the flowchart in Fig. 27. The ECU 900 may also receive an altitude signal for shifting the plot in Fig. 25 upwards or downwards when the vehicle is operating in a high altitude. Fig. 28 does not show the hydraulic fluid pressure signals and engine oil fluid pressure signal in Fig. 17. However, these features may be optionally included in a full operating embodiment of Fig. 28.

The ECU 900 in Fig. 28 preferably receives sensor output signals from at least the following sources:

1. an ambient air sensor in an air cleaner (clean side) or other suitable location;

2. a temperature sensor at the end of the engine block's temperature control fluid water jacket, or other suitable location;

3. an oil temperature sensor in the engine oil pan or a temperature indicative of the engine block or engine oil temperature;

4. an altitude sensor; and

5. an optional "High Engine Load" sensor.

The ECU 900 utilizes some or all of those sensor signals to generate open/close command signals for the fluid injectors of the EETC valve. Although Figs. 27 and 28 do not describe the operation of the restrictor/shutoff valves, it should be understood that these valves are also operated in accordance with the same principles as the EETC valve.

An added benefit of a system utilizing the multiple curves discussed above is that the time between oil changes can be increased. Frequent oil changes
become necessary when the internal engine temperature is not maintained at its optimum value during a significant percentage of driving time. The multiple curve system reduces this percentage, thereby prolonging the life of the oil.

Fig. 29 graphically shows the benefit of operating an engine in accordance with multiple curves. Fig. 29 shows a solid line plot of the optimum engine oil temperature at selected ambient air temperatures. (This is the same plot shown in Fig. 25.) Fig. 29 also shows a dashed line plot of the actual temperature of the engine lubrication oil measured in the oil pan of a GM 3800 transverse engine equipped with an EETC valve when the state of the EETC valve is controlled according to the curves shown in Figs. 24 and 26. (No "Extreme High Load Curve" is employed in the system which generates the plots in Fig. 29.) For comparison, Fig. 29 also shows a dashed/dotted plot of the actual temperature of the engine lubrication oil when coolant flow to the radiator is controlled by a prior art thermostat calibrated to open at about 195 degrees Fahrenheit (90.6 °C).

When the ambient air temperature is less than about 60 degrees Fahrenheit (15.6 °C), the EETC valve system significantly outperforms the prior art thermostat. That is, the EETC valve system maintains the actual engine oil temperature closer to the optimum value. When the ambient air temperature is greater than about 70 degrees Fahrenheit (21.1 °C), the capacity of the radiator limits the ability of the cooling system to maintain the engine oil temperature at its optimum value. Thus, no matter what kind of flow control valve is employed, the engine oil will run hotter than desired. However, as is shown in Fig. 29, an engine incorporating the present invention will still operate closer to the optimum engine curve at higher temperatures compared to the prior art thermostatic system. This is due to the better flow capacity provided by the EETC valve, i.e., 50% more flow capacity than a restrictive thermostat. The EETC valve of the present invention also opens up sooner when operating in hotter temperatures than the thermostatic system and, therefore, maintains the engine at the coolest possible operating temperature (as shown in Fig. 24).

When the ambient air temperature is in a sub-zero degree Fahrenheit (-17.8 °C) range, a prior art thermostat allows engine oil temperature to dip into a sludge forming range of temperatures. This occurs because the coolant temperature may reach
a level sufficient to cause the prior art thermostat to open, even when the internal engine temperature is significantly below its optimum operating value.

Fig. 29 also shows an Xed line plot which represents actual engine oil temperature in a system employing an EETC valve, restrictor/shutoff valves and an oil pan tube for delivering heat to the engine oil. Such a system maintains actual engine oil temperature very close to the optimum value, even in sub-zero Fahrenheit (−17.8 °C) ambient air temperatures. In ambient air temperatures above about zero degrees Fahrenheit (17.8 °C), the plot of such a system generally follows the plot of a system employing only the EETC valve.

Fig. 30 shows a trend line of TCF temperature and oil temperature during vehicle operation (and after engine start-up/warm-up). In this example, the ambient air temperature is about 40 degrees Fahrenheit (4.4 °C). According to the Fig. 25 plot, the optimum engine oil temperature at this temperature is about 240 degrees Fahrenheit (115.6 °C).

From time \( t_5 \) to \( t_6 \), the engine is operating under low load conditions and thus is following the "Normal Curve" in Fig. 24. The actual TCF temperature is about 220 degrees Fahrenheit (104.4 °C). The EETC valve is closed, as dictated by the "Normal Curve." The actual engine oil temperature is about 238 degrees Fahrenheit (114.4 °C), as expected from Fig. 29.

At time \( t_6 \), the vehicle engine begins to experience high load conditions. Almost immediately, the engine oil heats up and exceeds the optimum value in Fig. 25. Accordingly, the system shifts to the "High Load Curve" in Fig. 24. This causes the EETC valve to open, thereby allowing the TCF to flow to the radiator. Between times \( t_6 \) and \( t_7 \), the TCF temperature drops quickly and stabilizes at a lower value of about 180 degrees Fahrenheit (82.2 °C). During this time period, the lower TCF temperature causes the engine oil temperature to slowly drop after its quick rise. At time \( t_7 \), the engine oil temperature returns to 238 degrees Fahrenheit (114.4 °C) and the system shifts back to the "Normal Curve." This causes the EETC valve to close. Between times \( t_7 \) and \( t_8 \), the TCF temperature rises slowly. Between times \( t_8 \) and \( t_9 \), the engine oil temperature may continue to drop slowly and then rise due to a lag time until the warmer
TCF begins to heat the oil. Eventually, the engine oil temperature stabilizes at 238
degrees Fahrenheit (114.4 °C).

After time $t_0$, the trend lines repeat themselves so long as the high load
condition is still present. Thus, the system cycles between the "Normal Curve" and the
"High Load Curve." If the system is equipped with the optional "Extreme High Load
Curve," the frequency of cycling is tracked. If the frequency is too high, the system
begins to switch between the "Normal Curve" and the "Extreme High Load Curve,"
and ignores the "High Load Curve." If the high load condition ceases, the system
returns to the "Normal Curve" and the engine oil and TCF temperatures stabilize at the
time $t_0$ values.

Although the multiple curve embodiments rely on engine oil temperature
to determine when to switch curves, other internal engine temperature parameters may
be employed instead and are within the scope of the invention. For example, a
thermistor embedded in the engine block can be employed to obtain a more accurate
reading of the actual engine operating temperature.

Figs. 31A and 31B illustrates a novel optional oil heating feature for
the system described in Figs. 24-30. Fig. 31A is an idealized diagrammatic view of
the TCF circulation flow path through a GM 3800 V6 transverse engine equipped with
an EETC valve in the closed state. Fig. 31A is similar to prior art Fig. 40, except that
the prior art thermostat 1200 in Fig. 40 is replaced with EETC valve 100. Also, in Fig.
31A, the outlet of the water jacket 1202 does not flow directly into the inlet of the water
pump 1206, as in Fig. 40. Instead, the outlet of the water jacket 1202 flows into TCF
flow path 1300. This configuration was previously discussed with respect to Figs. 14A
through 14F. Hence, TCF flow path 1300 corresponds to passageway 216 in those
figures. The TCF flow path 1300 flows through oil pan 1302 and into the inlet of the
water pump 1206 in a series manner. Thus, preferably all of the TCF which leaves the
water jacket 1202 flows through the oil pan 1302 before it is returned to the water pump
1206 for recirculation. The TCF flow path 130 includes heat conductive tube 1304
which is similar to the heat conductive tube 220 shown in Fig. 18. For illustration
purposes only, Fig. 31 exaggerates the length of the conductive tube 1304 and the size
of the oil pan 1302.
In operation, preferably all of the TCF at the outlet of the water jacket 1202 flows through the heat conductive tube 1304 whenever the EETC valve 100 is closed. During engine start-up/warm-up, the EETC valve 100 is usually closed and the internal engine temperature is most likely colder than the optimum value. Since the TCF temperature in the water jacket 1202 rises more rapidly than engine oil temperature during engine start-up/warm-up, heat energy from the hotter TCF in the conductive tube 1304 is transferred to the engine oil in the oil pan 1302, thereby promoting faster engine warm-up.

Fig. 31B illustrates the temperature control system of Fig 31A when the EETC valve 100 is in the open position. Substantially all of the TCF is transferred through the valve to the radiator 208. However, a small amount of TCF may still transfer through the intake manifold to the oil pan if the EETC valve is designed so that it does not completely block the flow therethrough.

Figs. 32A and 32B illustrate an alternate embodiment of the temperature control system wherein the TCF can be utilized to cool the engine oil. Fig. 32A is an idealized diagrammatic view of the TCF circulation flow path through a GM 3800 V6 engine equipped with an EETC valve in the closed state and is similar to Fig. 31A. Fig. 32B illustrates the valve in its open state which completely obstructs the passage of the TCF into the intake manifold and the oil pan. Accordingly, all of the TCF will flow through the radiator 208 in this state.

Turning again to Fig. 30, when the engine experiences high load conditions and the engine oil exceeds its optimum value, the system shifts to the "High Load Curve." If the EETC valve 100 is not already open, it will most likely open, resulting in a relatively quick and sharp drop in the TCF temperature. If the TCF in the TCF flow path 1300 is cooler than the engine oil, the TCF circulating through the conductive tube 1304 will draw heat away from the engine oil, promoting engine oil cooling. This will shorten the time period between t₁ and t₂ in Fig. 30.

There may be instances when the EETC valve 100 is open and the engine oil temperature is already at or near the optimum value. In this instance, flow through the flow path 1300 is not desirable because it will cause unnecessary cooling of the engine oil. Although the flow path 1300 in Fig. 32A does not include a flow control
valve, such a valve may be employed to ensure that flow only occurs when the engine oil temperature exceeds the optimum value.

An added benefit of the extra flow path 1300 is that the heat energy in the TCF transfers to the oil pan 1302 when the engine is off. This helps to keep oil temperatures above sludge forming conditions when the vehicle is not in use. The system shown in Figs. 32A and 32B also will result in a more uniform temperature differential throughout the entire system, thereby resulting in a lower temperature of the TCF than the oil.

The EETC valve described herein can be employed with one or more restrictor/shutoff flow control valves to improve the temperature control function of the system over that which would be achieved when employing only the EETC valve, with or without its optional oil pan heating feature. As noted above, the restrictor/shutoff flow control valves 300 and 400 shown in Fig. 14A can be any type suitable for the task. One type of novel restrictor/shutoff flow control valve particularly suitable for this task is shown in Figs. 33-39 and disclosed in U.S. Patent 5,458,096.

The restrictor/shutoff valves can be employed in an anticipatory mode to lessen the sudden engine block temperature peaks caused when a turbocharger or supercharged is activated, in the same manner as the anticipatory mode described above with respect to the EETC valves. When the turbocharger or supercharger is activated, a signal can be immediately delivered to the restrictor/shutoff valves to cause the valves to be placed in their unrestricted/unblocked state, if they are not already in that state. A short time after the turbocharger or supercharger is deactivated, the valves can then be returned to the state dictated by the ECU.

In extremely hot ambient air conditions, a system wherein the states of the EETC valve and restrictor/shutoff valves are controlled according to one or more of the curves will perform better upon engine start-up than a cooling system having a thermostat controlled solely by coolant temperature. This is because the curves allow the designer to anticipate expected engine operating conditions based on the present TCF and ambient air temperature. Accordingly, the EETC valve can be immediately opened and the restrictor/shutoff valves can be immediately placed in an unblocked/unrestricted
state in anticipation of an expected engine operating condition that would call for such states.

Consider, for example, a prior art vehicle which has been sitting in the sunlight when the ambient air temperature is 100 degrees Fahrenheit (37.8 °C). In such an environment, the underhood and vehicle interior is likely to be at least 120 degrees Fahrenheit (48.9°C). The coolant temperature will likely be at least 100 degrees Fahrenheit (37.8 °C). When the driver enters the vehicle and starts the engine, the air conditioning is typically immediately turned on to its maximum setting. Due to the hot conditions and the extra stress on the engine due to the air conditioning system, the coolant temperature quickly rises. Although it is virtually certain that the coolant will need to flow to the radiator to keep the engine block at an optimal operating temperature, the thermostat must nevertheless wait until the temperature has reached the appropriate level before it opens to allow flow to the radiator. The result is that full engine cooling is temporarily delayed. If the vehicle is equipped with a prior art wax pellet type or bimetallic coil type thermostat, there will an even greater delay before the coolant can flow to the radiator due to thermostat hysteresis. These delays may cause a sudden engine block temperature peak which, in turn, may cause the coolant temperature and engine oil temperature to temporarily reach levels which exceed the ideal range.

However, if the vehicle is equipped with a novel EETC valve and/or restrictor/shutoff valves controlled by the programmed curve, all of the TCF will immediately flow through the radiator upon engine start-up. Accordingly, the likelihood of a sudden engine block temperature peak will be reduced. This is because the curves shown in Figs. 19, 20, 22A, 22B, 24 and 26 indicate that at an ambient temperature of 100 degrees Fahrenheit (37.8 °C) and a TCF temperature above 100 degrees Fahrenheit (37.8 °C), the EETC valve should be in the open state and the restrictor/shutoff valve should be in the unblocked/unrestricted state. Of course, there will be a two or three second delay before the valves can be placed in these states after starting the engine to allow the hydraulic fluid system to reach proper operating pressure. This anticipatory feature is an inherent benefit of controlling the state of a flow control valves according to a programmed curve.
As discussed above, in one embodiment of the invention, the ECU receives signals indicative of the ambient air temperature, the engine oil temperature, and the temperature control fluid temperature. The ECU compares these signals to one or more temperature control curves. In the preferred embodiment, the ECU compares the engine oil temperature to an optimum engine oil temperature curve. The ECU determines the operating state of the engine based on this comparison (e.g., normal, high or extremely high load). The ECU then compares the actual temperatures of the ambient air and the temperature control fluid to a curve or set of predetermined values for determining the desired state or position of the flow control valves (e.g., EETC valve, restrictor valves). The set of predetermined values preferably defines a curve which is a function of at least ambient air temperature and temperature control fluid temperature. A portion of the preferred curve has a non-zero slope. The ECU sends control signals to the solenoids to open and close the hydraulic fluid injectors. This, in turn, causes the opening and closing of the flow control valves as required.

In an alternate embodiment of the invention, the ECU compares the actual oil temperature against an optimum engine oil temperature value or series of values defining a curve. If the actual oil temperature is above the optimum or desired engine oil temperature value, then the ECU adjusts the Normal temperature control curve instead of switching to a High Load curve. Specifically, the ECU shifts the Normal temperature curve downward a predetermined amount so as to reduce the temperature of the temperature control fluid which causes actuation of the valves between their states or positions. In one embodiment of the invention, for every one degree Fahrenheit (0.56 °C) that the actual engine oil temperature is above the optimum engine oil temperature there is a corresponding two degree Fahrenheit (1.1 °C) decrease in the temperature control fluid temperature component which produces actuation of the valves. This effectively results in a downward shifting of the temperature control curve. Different engine configurations will, of course, result in different amounts that the temperature control fluid temperature component is shifted downward for a one degree rise in actual engine oil temperature. For example, a one degree rise in actual oil temperature above the optimum oil temperature value may produce a decrease in the actuation temperature of the temperature control fluid within a range of between about one and ten degrees.
Furthermore, it is contemplated that the amount of downward shifting of the temperature component may not be constant (e.g., the amount of downward shifting may increase as the difference between the actual oil temperature and the optimum oil temperature increases).

In yet another embodiment, the amount of downward shifting of the temperature control fluid temperature component may also vary with changes in ambient temperature. For example, at 0 degrees Fahrenheit (-17.8 °C) ambient air temperature, every one degree that the actual oil temperature is above the optimum oil temperature produces a one degree decrease in the temperature control fluid temperature component.

At 50 degrees Fahrenheit (10 °C) ambient air temperature, every one degree that the actual oil temperature is above the optimum oil temperature produces a two degree decrease in the temperature control fluid temperature component. At 80 degrees Fahrenheit (26.7 °C) ambient air temperature, every one degree that the actual oil temperature is above the optimum oil temperature produces a three degree decrease in the temperature control fluid temperature component. This embodiment of the invention may be graphically illustrated as shown in Figure 45A wherein a control curve is selected by the ECU depending on the sensed ambient temperature. A plurality of control curves could be plotted representing a range of ambient temperatures. For example, control curves could be plotted from about -60 degrees Fahrenheit (-51.1 °C) to about 110 degrees Fahrenheit (43.3 °C), each having an associated adjustment factor for adjusting the temperature control fluid temperature component and/or for shifting the set of predetermined values. The adjustment factors may vary. The ECU may also be configured to interpolate between designated curves of providing an accurate adjustment factor. Although linear curves are illustrated in the exemplary embodiment, it should be understood that alternate non-linear curves may be incorporated for each ambient temperature. It is also contemplated that a single curve may be utilized for shifting the temperature control curve. One axis of the plot would represent the sensed ambient temperature. The second axis would represent the ratio of a one degree increase in engine oil over the corresponding downward shifting of the temperature control curve (e.g., 1/1, 1/2 or 1/3).
Alternately, it may be preferable to wait until the actual engine oil temperature exceeds the optimum engine oil temperature value by a set amount before altering the temperature control curve. For example, for every 3 or 5 degree increase in the actual engine oil temperature above the optimum oil temperature value there is a corresponding decrease in the set point temperature of the temperature control fluid which directs actuation of the valve. Figure 45B graphically illustrates this aspect of the invention. A series of identical temperature control curves are shown for a plurality of actual sensed engine oil temperatures. Each dashed line (NC') represents a shifted-down version of the solid "normal" temperature control curve (NC). It should be readily apparent that only one particular curve or value would be utilized for a given sensed engine oil temperature. In an alternate arrangement, an equation and/or scaling factor instead of a separate curve may be utilized to alter the value at which actuation occurs according to the normal curve.

In many instances, altering the temperature control fluid component based only on the amount that the actual engine oil temperature exceeds the optimum engine oil value would be sufficient. However, in the preferred embodiment, it is also desirable to monitor the engine load to determine how much altering of the temperature control curves is required to maintain the actual engine oil temperature at or near the optimum oil temperature.

One method for varying or altering the temperature control curve as a function of engine load is by monitoring the rate of change of the actual engine oil temperature. Referring to Figure 45C, an exemplary curve is illustrated which depicts the rate of change of the actual engine oil temperature versus the scaling or adjustment factor for the temperature control fluid temperature component and/or for determining the downward shifting of the set of predetermined values. If the detected rate of change of the actual oil temperature is relatively low (R₁), the downward shifting of the temperature control curves is also small (S₁). If, on the other hand, the detected rate of change of actual oil temperature is large (R₂) which is indicative of a high loading condition, then the downward shifting of the temperature control curve is also relatively large (S₂). Although the exemplary curve depicts a linear curve other curve shapes, such as exponential, logarithmic, curvilinear, etc., may be substituted therefor. Furthermore,
a step function may instead be utilized which provides a different amount of downward shifting of the temperature control curve for different detected rates of change of the actual engine oil.

During use, when the engine computer detects that the actual sensed oil temperature exceeds the optimum oil temperature, the computer then determines rate of change of the actual engine oil temperature. The engine computer determines a scaling or adjustment factor from this rate of change. The adjustment factor is then applied to the normal temperature curve to shift the curve downward. The engine computer continues to monitor the rate of change in the actual oil temperature and shifts the temperature control curve accordingly. Delays can be incorporated into the system to minimize the amount of shifting of the temperature control curve that occurs.

An analytically determined curve illustrating the effect of the above embodiment is shown in Figure 46. The curve shown is for a constant ambient temperature of 60°F (15.6°C). From time t₀ to time t₁, the engine computer controls the opening and closing of the EETC valve and restrictor valves according to a normal temperature control curve (level 1). At time t₁, the engine computer detects an increase in the actual oil temperature above the optimum engine oil temperature value (approximately 235°F (112.8°C) in the illustrated embodiment) which is preferably determined from an optimum engine oil temperature curve similar to the one shown in Figure 25. The engine computer either applies a predetermined factor for downward shifting of the temperature control curve (e.g., 2 degree drop in TCF for each 1 degree rise in engine oil temperature) or, more preferably, the engine computer determines a rate of change of the engine oil temperature and from that rate calculates the amount of downward shifting of the temperature control curve required.

The EETC valve is opened according to the new shifted temperature control curve (level 2), causing the immediate drop in the temperature control fluid as shown between time t₁ and t₂. The engine oil however, will continue to rise until the cooling effect of the temperature control fluid begins to cool the engine oil.

The engine computer continues to monitor the actual engine oil temperature. At time t₂, the temperature of the temperature control fluid stabilizes at the new shifted temperature control fluid valve. If the actual engine oil is still above
the optimum engine oil temperature, the engine computer determines the rate of change of engine oil temperature between time \( t_1 \) and \( t_2 \). The high rate of change indicates a continued high engine load condition. Accordingly, based on this determined rate, the engine computer determines an additional amount of downward shifting of the temperature control curve that is required. The flow control valve or valves are then controlled based on the this second shifted temperature control curve (level 3).

At time \( t_3 \), the engine computer determines a rate of change of the engine oil temperature between time \( t_2 \) and \( t_3 \). Since the new rate of change in the illustrated example is less than the previous rate of change, the engine computer does not shift the temperature control curve downward. Instead, the engine computer continues to control the flow control valve or valves based on the level 3 temperature control curve.

At time \( t_4 \), the engine computer determines a rate of change of the engine oil temperature between time \( t_3 \) and \( t_4 \). Since the new rate of change in the illustrated example is decreasing, the engine computer shifts the temperature control curve upward back toward the first or normal level. As a result, the temperature control fluid temperature continues to heat up while the engine oil decreases in temperature and begins to return to its optimal operating temperature.

Since the reheating of the temperature control fluid is a slow process, as illustrated by the time period between time \( t_3 \) and \( t_4 \), it is important not to drop the temperature control fluid to an unnecessarily low temperature so as to maintain the engine oil as close to the optimum engine oil as possible.

It should be understood that the sensed ambient air temperature will affect rate or slope of the temperature control fluid temperature curve in Figure 46. For example, at hot ambient temperatures, the temperature slope of the temperature control fluid between time \( t_4 \) and \( t_5 \) will be steeper than at low ambient temperatures. This is due to the fact that at lower temperatures (e.g., zero degrees ambient) it is more preferable that the engine oil remains at a higher temperature for a longer period of time to increase heater and defroster capabilities. The cold ambient temperature reduces the likelihood that the engine oil will become excessively hot. In warmer ambient temperatures, it is desirable to maintain the engine oil closer to its optimum valve so
as to prevent overheating. The temperature slope of the temperature control fluid is, thus, steeper at these warmer temperatures.

An alternate method for determining the engine load is by monitoring the intake manifold vacuum pressure. The sensed intake manifold pressure generally provides an accurate indication of the current engine load. For example, if the sensed intake manifold vacuum pressure is less than about 4 inches Hg (13.5 kPa), the engine is operating under a high load condition. Accordingly, a first predetermined adjustment factor or curve can be selected for reducing or replacing the temperature control curve. If, however, the intake manifold vacuum pressure is less than about 2 inches Hg (6.77 kPa), then the engine is operating under an extremely load condition. In this case, a second adjustment factor is selected for varying the normal temperature control curve.

Yet another method for determining engine load is through the monitoring of the commanded engine acceleration. For example, a high commanded engine acceleration is indicative of a high engine load condition. The amount of engine acceleration can be determined from a variety of methods, such as the accelerator pedal displacement, a signal from the fuel injection system, etc. Depending on the commanded acceleration, a predetermined factor and/or curve is selected for varying the normal temperature control curve.

In both the commanded engine acceleration method and the intake manifold vacuum pressure method, a rate monitoring system similar to the one discussed above with respect to the engine oil temperature could also be incorporated to further optimize these methods.

Figure 47 is an actual plot of the present invention incorporated into a GM 3800 V6 engine. The data was recorded as the vehicle was being driven up a very steep incline. The data which is shown is the engine oil temperature (curve A), the temperature of the temperature control fluid (curve B), the temperature of ambient air (curve C), the speed of the vehicle (curve D) and the vacuum pressure (curve E). The X axis represents a time period of several minutes. At point Z₁, an acceleration was commanded by the vehicle, increasing its speed from approximately 55 miles per hour to over 90 miles per hour (88 km/h - 145 km/h). The increase in engine speed and acceleration results in a corresponding decrease in vacuum pressure and an increase in
the temperature of the engine oil. The temperature control system detects the increase in engine oil temperature and, accordingly, reduces the temperature of the temperature control fluid. At point $Z_2$, the lower temperature of the temperature control fluid begins to reduce the temperature of the engine oil. Figure 47 clearly illustrates the interrelationship between detected engine load conditions (acceleration, velocity, and/or vacuum pressure) and the engine oil and temperature control fluid temperatures.

Based on the above discussion, those skilled in the art would readily understand and appreciate that various modifications can be made to the exemplary embodiments disclosed and are well within the scope of this invention. For example, the temperature control curves themselves may be replaced by one or more equations for controlling the actuation of the valves. In yet another embodiment, fuzzy logic controllers could be implemented for controlling the actuation of the valves and/or varying of the temperature control curves.

The varying or downward shifting of the temperature control curves as discussed above is preferably limited to between approximately $50^\circ$F - $70^\circ$F ($27.8^\circ$C - $38.8^\circ$C). This is intended to prevent substantial degradation in the capabilities of the heater/defroster systems by maintaining the temperature control fluid at a reasonably high temperature.

The above methods for adjusting the temperature control curves can also be utilized in the start up/warm up phase. For example, if the actual engine oil temperature is below the desired or optimum engine oil temperature by a predetermined amount, an adjustment factor can be applied to the temperature control curve to shift it upward a preset amount. Preferably, the amount of adjustment would also vary with the ambient air temperature such that the shifted temperature control curve would be similar to the start-up/warm-up curve shown in Figure 26.

The above discussion has been directed toward a temperature control system which controls engine oil temperature so as to maintain it at or near its optimum temperature. However, it is contemplated that, in certain cases, optimal control may not be necessary. In light of this, another embodiment of the present invention is disclosed which does not utilize curves that vary with ambient temperature for controlling actuation of the valves. Instead, one or more predetermined engine oil and/or
temperature control fluid temperature values are utilized for controlling the valves regardless of ambient air temperature. The predetermined engine oil and temperature control fluid temperatures are preferably chosen so as to provide an acceptable temperature state for the engine over a wide range of ambient temperatures. For example, an average engine oil temperature value of approximately 260°F (126.7°C) may be utilized as the predetermined value.

Referring to Figure 48, a graphical illustration of this embodiment of the invention is shown. In this embodiment, the temperature control system is operated so as to maintain the engine oil at or near at least one engine oil temperature value (designated by the letter 'A'). The operation of the system is as follows. A sensor within the engine detects a temperature indicative of the temperature of the engine oil. This may be accomplished, for example, by directly sensing the temperature of the oil within the oil pan, or by sensing the temperature of the engine block or the oil pan itself. This signal is sent to the engine computer. The engine computer compares the signal to a predetermined engine oil temperature value. If the sensed oil temperature signal is less than the predetermined engine oil temperature value, the engine oil is in a relatively cold state. In this state, it is not desirable to circulate a flow of temperature control fluid. The engine computer may be utilized to determine the position of the valve controlling the flow of temperature control fluid between the radiator and the engine (e.g., EETC valve). The engine computer can determine the position of the valve many different ways. One way involves providing signals from the valve which indicate its position. If the valve is in its open position (allowing flow of temperature control fluid between the radiator and the engine) then it is desirable for engine computer to send signals to cause the valve to close (inhibiting flow of temperature control fluid from the radiator).

In the above discussion, the engine computer determines the position of the valve and automatically closes the valve based on only the temperature of the engine oil. However, it is contemplated that the engine computer may also utilize the temperature of the temperature control fluid for controlling the opening and closing of the valve. By utilizing the temperature of the temperature control fluid the system can more readily account for the lag time involved in heating the oil (i.e., engine heats up
quicker than engine oil) In this embodiment, a signal indicative of the actual or sensed temperature of the temperature control fluid is sent to the engine computer. The engine computer compares this signal (or temperature) against at least one predetermined temperature control fluid temperature value. If the actual sensed temperature is below the predetermined temperature control fluid temperature value then the valve is likely in its closed position inhibiting flow between the radiator and the engine. By leaving the valve in its closed position, the temperature of the engine oil will rise since there is no cooling being provided by fluid from the radiator.

If, on the other hand, the sensed temperature of the temperature control fluid is greater than the predetermined temperature control fluid temperature value, then the valve be in its open position allowing temperature control fluid to circulate from the radiator into the engine. However, since the temperature of the engine oil is relatively cold, it is desirable that the valve be placed in its closed position. In order to close the valve (if it is not already in its closed position), the engine computer shifts the predetermined temperature control fluid temperature value upward a prescribed amount. This is equivalent to adjusting or increasing the predetermined temperature value. The amount of shifting or adjusting may depend on various factors. Preferably, the amount of upward shifting is a function of the amount that the actual engine oil temperature is below the predetermined engine oil temperature value. A detailed discussion has already been provided hereinabove on shifting or adjusting predetermined temperature values or components.

It may instead be desirable to adjust or increase the predetermined temperature control fluid temperature value an amount that will automatically place it above the actual temperature control fluid temperature, regardless of the comparison of the actual engine oil temperature to the predetermined engine oil temperature value. The engine computer would then maintain the predetermined temperature control fluid value at that temperature (or above) until the actual engine oil temperature reaches the predetermined engine oil temperature value. In another embodiment, the engine computer does not adjust the predetermined temperature control fluid temperature value but simply maintains the valve in the closed position until the actual engine oil temperature reaches the predetermined engine oil temperature value.
When the engine computer receives an engine oil temperature signal which is above the predetermined engine oil temperature value, then engine is in a relatively hot state. In this state it is desirable to circulate cool temperature control fluid from the radiator through the water jackets surrounding the engine. As discussed above, the engine computer may be utilized to determine the position of the valve and then automatically place the valve in a desired position (e.g., open). However, in one preferred embodiment, the engine computer also utilizes the actual or sensed temperature of the temperature control fluid. The engine computer compares the temperature of the temperature control fluid to at least one predetermined temperature control fluid temperature value. If the actual sensed temperature is above the predetermined temperature control fluid temperature value, then the valve should already be in its open position allowing temperature control fluid flow between the radiator and the engine. However, if the sensed temperature of the temperature control fluid is less than the predetermined temperature control fluid temperature value, then the valve is likely to be in its closed position. It is therefore desirable to open the valve so as to cool the engine. In order to do so, the engine computer shifts or adjusts the predetermined temperature control fluid temperature value downward a prescribed amount in a similar manner as described above. When the actual temperature of the temperature control fluid exceeds the shifted or adjusted predetermined temperature control value, the valve will open.

Figure 48 also illustrates upper and lower temperature control fluid temperature limits (letters 'C' and 'D'). These temperature limits prevent the temperature control system from significantly reducing the effectiveness of the heater/defrost system.

The preferred temperature control system utilizes the engine computer to continuously shift or adjust the predetermined temperature control temperature value based on the comparison of the actual engine oil temperature value to the predetermined engine oil temperature value. Thus, the shifted or adjusted predetermined temperature control value may not necessarily cause immediate actuation of the valve. Instead, the new shifted value may simply be closer, temperature-wise, to the actual temperature resulting in quicker actuation of the valve. In an alternate, but not preferred
embodiment, the predetermined temperature control fluid temperature value is not adjusted. Instead, the sensed or actual temperature control fluid temperature is adjusted and then compared against the predetermined temperature control fluid temperature value. Those skilled in the art would readily be capable of practicing alternate methods for controlling the temperature control system based on the engine oil temperature. These alternate methods are well within the purview of the claims.

In operation, the above system functions as follows. During initial start-up, if the engine computer senses that the engine oil temperature is less than approximately 230°F (110°C), the engine computer raises or sets the predetermined temperature control fluid temperature value to approximately 240°F (115.6°C) until the engine computer detects that the engine oil temperature is at or near approximately 230°F (110°C) which is its normal operating temperature.

If the engine computer subsequently determines that the engine oil temperature is greater than approximately 230°F (110°C), the computer shifts the predetermined temperature control fluid temperature value from its normal operational value (e.g., approximately 200°F (93.3°F)) to a lower value. The shifting is achieved by decreasing the predetermined temperature control fluid temperature value 2°F (1.1°C) for every 1°F (0.56°C) that the actual engine oil temperature exceeds the predetermined engine oil temperature value. The downward shifting of the predetermined temperature control fluid temperature value is limited to approximately 170°F (76.7°C).

If after reaching the normal engine oil operating temperature, the engine computer subsequently determines that the engine oil temperature is less than approximately 230°F (110°C), the computer shifts the predetermined temperature control fluid temperature value from its normal operational value (e.g., approximately 200°F (93.3°C)) to a higher value. The shifting is achieved by increasing the predetermined temperature control fluid temperature value 2°F (1.1°C) for every 1°F (0.56°C) that the actual engine oil temperature is below the predetermined engine oil temperature. The upward shifting of the predetermined temperature control fluid temperature value is limited to approximately 240°F (115.6°C).

It is also contemplated that the control logic for the temperature control system may be incorporated into computer chips or processors mounted directly in the
valve instead of in the engine computer. Hence, while the above discussion has concentrated on utilizing an engine computer for controlling the valves, it is also contemplated that other electronic control mechanisms may be utilized in its stead.

Although the EETC valves disclose fluid injectors which are integrated into the valve housing, the scope of the invention includes an embodiment wherein the fluid injectors are physically separated from the reciprocating EETC valve components and connected by fluid lines therebetween. Likewise, the fluid injectors associated with the restrictor/shutoff valves can be either integrated into the valve housing as shown in Fig. 38, or can be physically separated from the reciprocating valve components as shown in Figs. 33 and 34. Alternatively, fluid injectors associated with an integrated valve such as shown in Fig. 38 can control the state of other restrictor/shutoff valves which do not have their own fluid injectors.

While the preferred embodiment utilizes an ECU to provide pressurized hydraulic oil to the EETC valve for actuating the valve member 146, a simpler and less precise means for providing the pressurized fluid is by mounting a thermostat-type device within the hydraulic fluid lines leading to and from the EETC. The thermostat would provide pressurized hydraulic fluid when the oil in the line or in the pan exceeds a prescribed temperature which, in the preferred embodiment, is chosen to be indicative of the engine oil temperature. A drawback to this type of a system is that a mechanism must be added to the system which removes or release the oil in the EETC valve when it is desired to close the valve, i.e., depressurize the diaphragm.

As stated above, the preferred valve in the present invention is operated through the use of hydraulic fluid. However, other types of valves may also be utilized within the scope of this invention. For example, referring to Fig. 49, an electronically assisted thermostat 950 is illustrated which can be utilized in one embodiment of the present invention. The electronically assisted thermostat 950, to an extent, is configured and operates similar to a conventional thermostat. The conventional portion of the electronically assisted thermostat 950 includes an outer housing 952, a valve member 954, a wax pellet 956, and a return spring 958. The wax pellet 956 is designed to maintain the valve member 954 in a closed position when the wax pellet 956 is solidified. The return spring 958 is configured to bias the valve member 954 into an open position.
when the wax pellet 956 is melted. The details of the configuration and operation of conventional thermostats is well known to those skilled in the art.

The electronically assisted thermostat 950 also includes a heating element 960, such as a coil, which extends around or through the wax pellet 956. The heating element 960 is electrically connected to a power source (not shown) through an electrical cable 962. A computer, such as the ECU 900, controls the transmission of electric current along the cable 962 to the heating element 960. The heating element 960 is designed to heat up to an elevated temperature when current is supplied to it. The heat from the heating element 960 exposes the wax pellet 956 to an approximately 80 degree Fahrenheit (44.4 °C) temperature increase. This assists in melting the wax pellet 956 sooner than it would otherwise melt. Heating elements, such as dielectric heaters and resistance heaters, are well known in the art and, thus, no further details are required.

In order to operate more efficiently in the present system, the wax pellet 956 is calibrated to begin to open between 220°F and 226°F (104.4°C and 107.8°C) and to be fully open at a fluid temperature between 236°F and 240°F (113.3°C and 115.6°C). These temperatures are higher than current thermostat designs (e.g., approximately 180°F (82.2°C)). However, maintaining the temperature control system as a closed circuit (i.e., no radiator) until the temperature control fluid reaches 220°F (104.4°C) produces increased pressure (approximately 7 psi (48.263 kPa)) in the system.

To accommodate this increased pressure, the wax pellet 956 is preferably manufactured slightly larger than conventional pellets. A larger return spring 958 and housing 952 may also be necessary.

The ability of the heating element 960 to melt the wax pellet 956 80°F (44.4°C) before it would normally melt permits control over the temperature control fluid flow for a variety of temperature control fluid temperatures. The 80°F (44.4°C) temperature limit on the heating element 960 provides the lower limit at which the valve member 954 can be opened (e.g., lower temperature limit of 160°F (71.1°C)). This helps prevent loss of the heater and defrost capabilities of the system. The upper temperature limit is maintained at 240°F (115.6°C) by the melt temperature of the wax pellet 956 itself.
The operation of one preferred embodiment of the electronically assisted thermostat 950 will now be discussed. The ECU 900 receives a signal indicative of the actual engine oil or block temperature. If actual engine temperature is less than a predetermined engine temperature value (e.g., the desired engine oil temperature value for a given sensed ambient air temperature), the thermostat operates in a conventional manner (e.g., initial opening when the temperature control fluid reaches 220°F/226°F (104.4°C/107.8°C)). If, however, the actual engine temperature is greater than the predetermined engine temperature value, the ECU 900 controls the transmission of current along the cable 962. The current results in heating of the heating element 960 which, in turn, causes the wax pellet 956 to begin to melt, thereby initiating opening of the thermostat.

The electronically assisted thermostat 950 described above provides a simple, lightweight device for efficiently controlling the flow of temperature control fluid.

The inlet hydraulic fluid injector employed in the novel EETC and restrictor/shutoff valves must tap into a source of pressurized hydraulic fluid to fill the respective valve chambers. Typical valves will tap into that source for about six seconds to fully change state. A slightly longer time period may be required for systems where a single injector fills the chambers of multiple restrictor/shutoff valves. These time periods are very short compared to the average length of a vehicle trip. Since valve states are unlikely to be changed more than a few times during a normal vehicle trip, the percentage of time that the pressurized source is tapped is anticipated to be very small, typically under one minute for every hour of driving, or less than 2%. Accordingly, there should be little, if any, effect on the normal functioning of the hydraulic fluid system. Thus, if the engine lubrication oil pump outlet lines are the source of the hydraulic fluid, the operation of the novel valves should not have any significant effect on the normal operation of the lubrication system. Nor should it be necessary to modify existing oil pumps or lubrication systems to accommodate the novel valves. The lines may tap off of the cylinder head or the block itself if desired, thus, requiring very little change to the existing engine envelope.
The preferred novel EETC and restrictor/shutoff valves described above reciprocate between a first position for allowing unrestricted flow of fluid through at least one passageway and a second position for restricting the flow through the passageway. The flow restriction is either partial or complete (i.e., 100 percent). Each of the valves are biased in one of the positions by a biasing spring and placed in the other position by hydraulic fluid pressure pushing against a piston member. In the EETC valves, the piston member is, preferably, either a diaphragm or a piston shaft. In the restrictor/shutoff valve, the piston member comprises a combination of a separate piston and shaft.

Although the EETC and restrictor/shutoff valves are shown as having a first position associated with a pressurized, fully filled chamber and a second position associated with an unpressurized, empty chamber, each of the valves can be designed to operate in reverse. That is, the position of the chambers and biasing springs can be reversed so that the valve is in a first position when the chamber is unpressurized and empty and is in a second position when the chamber is pressurized and fully filled. The scope of the invention includes such reversed configurations.

Likewise, the scope of the invention includes embodiments wherein the EETC and restrictor/shutoff valves are placed in positions between the first and second positions by only partially filling and pressurizing the respective chambers. To achieve a desired mid-position for a particular valve, chamber pressure values and/or filling or emptying time periods must be empirically determined for that valve. For example, if a particular EETC valve is fully opened by pressurizing the chamber to 25 psi (172 kPa) and continuing to pressurize for two seconds after the chamber reaches 25 psi (172 kPa), a procedure of pressurizing until the chamber reaches 15 psi (103 kPa) might place the valve in the desired mid-position. Alternatively, if it is desired to move an open EETC valve to a mid-position, partial chamber depressurization could be employed. Again, the particular pressure values and additional time periods must be empirically determined for a given novel valve. Once those values are determined, the ECU can be pre-programmed with the values to achieve the desired mid-position(s). Alternatively, a feedback control system employing valve position transducers connected to the ECU could be employed.
While the temperature control system of the present invention has been described as replacing the thermostat of an internal combustion engine, the system can also be utilized in conjunction with the a standard thermostat. An embodiment of this type would, preferably, incorporate a EETC valve in series with the thermostat. That is, the fluid line to the radiator would have both a standard thermostat mounted thereon, as well as an EETC valve. An ECU would determine when the EETC valve will have control over the fluid flow. Preferably, the EETC valve would control the initial start-up/warm-up mode of the engine, which is when the thermostat does not operate efficiently. In this mode, a means for inhibiting the thermostat would have to be incorporated to prevent the thermostat from opening the line to the radiator before the engine approaches its optimum temperature. For example, a pin could be actuated to lock the valve of the thermostat in the closed position. The actuation of the pin would be controlled by the ECU based on one or more of the valve control curves discussed above. Accordingly, the EETC valve would be in control of the system until the TCF fluid reaches its normal operating temperature whereupon the EETC valve would be inhibited from further control and the thermostat would be released to control the system as is commonly performed. The thermostat could also be locked out when the ambient temperature falls below a predetermined temperature, such as zero degrees Fahrenheit (-17.8 °C).

It is envisioned that this embodiment would be utilized in situations where retrofitting of an existing engine is more desirable then fully implementing the disclosed temperature control system. Since the temperature control system disclosed provides significant benefits during start-up/warm-up and at low temperatures, the modified embodiment discussed above has advantages over a standard thermostatic system.

Another feature of the present invention is the ability to control various other engine parameters in combination with the control of the TCF. For example, it is possible to control the electric fan which provides cooling for the radiator. When the temperature of the TCF measured at the outlet of the radiator is approximately between about 150 degrees and 160 degrees Fahrenheit (65.6 °C - 71.1 °C), and the vehicle speed is less than about 35 miles per hour (56.3 km/h), the fan is designed be operative. This corresponds to the operational state wherein the car is moving relatively
slowly and the TCF is being to become hot car. It is typically in this operational state where most overheating will occur. When the car is traveling above 35 miles per hour (56.3 km/h), the air flowing through the radiator and around the engine block will function to reduce the TCF temperature. Variations on the control of the fan are also possible. The ECU can be programmed to provide the fan control or, instead, a separate fan control unit may be utilized.

It is also possible to control the spark generated by the spark plug utilizing signals from the ECU. For example, the temperature of the TCF in the radiator and the ambient air temperature can be monitored to determine how much spark is required to produce the optimum combustion of the fuel. It is preferable to utilize the TCF temperature in the radiator since this valve should be relatively stable as compared with the TCF temperature out of the engine block which may vary significantly. Those skilled in the art would readily understand that other modifications can be made to the operational state of the internal combustion engine when utilizing the novel system disclosed.

The temperature control system of the present invention provides additional consequential benefits. By providing the means to increase the actual temperature of the TCF fluid in cold temperature environments (see Fig. 23), the physical size of the heater can be decreased. This is because the hotter the temperature of the TCF, the less heater core surface area required to extract the necessary amounts of heat energy from the TCF to warm the vehicle's passenger compartment.

An engine employing the EETC valve and one or more restrictor/shutoff valves will have less engine out exhaust emissions and greater fuel economy than a prior art engine cooling system employing only a prior art thermostat. Since the reduction in emissions and improvement in fuel economy will be greatest in cold temperature environments and during engine start-up, the invention offers the possibility to significantly reduce vehicle exhaust pollution levels. An engine incorporating the novel EETC and restrictor valves should also produce increased horsepower at lower temperatures.

Currently, the United States Environmental Protection Agency conducts its emissions testing in relatively warm ambient air temperatures. Testing in these warm
temperatures does not expose the actual polluting effects of vehicles when they are started and operated in cold temperature climates. For example, the current testing procedure requires that a vehicle "cold soak" in an ambient air temperature of 68 to 80 degrees Fahrenheit (20 °C - 26.7 °C) for 12 hours. That is, the vehicle must sit unused for 12 hours in this temperature environment so that the engine parts stabilize to that ambient air temperature. Then, the engine is started and emissions are measured to verify that they are within acceptable limits. Since the ambient air temperature is relatively warm, the engine and catalytic converter quickly heat up to an efficient operating temperature. Most vehicles today would fail the current emissions standards if the "cold soak" test was required to be performed in significantly lower ambient air temperatures, such as 28 to 40 degrees Fahrenheit (-2.2 °C to 4.4 °C). An engine employing the EETC valve along with restrictor/shutoff valves or the engine block by-pass system illustrated in Figs. 44A and 44B, will show a substantial improvement over current systems towards meeting current emissions standards under a "cold soak" test at such lower ambient air temperatures.

The inventions disclosed above provide an effective way to harness the underestimated one-third of heat energy handled by a vehicle's cooling system (see the excerpt in the Background of the Invention from page 169 of the Goodheart-Willcox Automotive Encyclopedia). The EETC valve, the restrictor/shutoff valve, and the use of programmed curves for determining their states are the basic building blocks for an engine temperature control system that effectively tailors the performance of the engine cooling system with the overall needs of the vehicle.

The present invention may be embodied in other specific forms without departing from the spirit or essential attributes thereof and, accordingly, reference should be made to the appended claims, rather than to the foregoing specification, as indicating the scope of the invention.
Claims

1. A temperature control system in a liquid cooled internal combustion engine equipped with a radiator and an engine, the system comprising:

   a flow control valve for controlling flow of a temperature control fluid along a passageway which is in communication with the radiator, the flow control valve having a first state for inhibiting said flow and a second state for allowing said flow;

   a sensor for sensing a temperature indicative of engine oil temperature and for providing an engine oil temperature signal; and

   an engine computer for receiving the engine oil temperature signal, the engine computer comparing the engine oil temperature signal to a predetermined engine oil temperature value, the engine computer providing signals for controlling the actuation of the flow control valve between its first and second states as a function of the comparison of the engine oil temperature signal to the predetermined engine oil temperature value.

2. A temperature control system according to claim 1 wherein the engine computer controls the flow control valve so that the valve is in its first state when the engine oil temperature signal is less than the predetermined engine oil temperature value and in its second state when the engine oil temperature signal is greater than the predetermined engine oil temperature value.

3. A temperature control system according to claim 1 or 2 further comprising:

   a sensor for sensing ambient air temperature and for providing an ambient air temperature signal indicative thereof; and

   the engine computer receiving the ambient air temperature signal, the engine computer determining the predetermined engine oil temperature value by comparing the ambient air temperature signal to a set of engine oil temperature values which vary as a function of ambient air temperature.
4. A temperature control system according to claim 1, 2 or 3 further comprising:

   a sensor for sensing a temperature indicative of the temperature control
   fluid temperature and for providing a signal indicative thereof; and

   wherein the engine computer receives the temperature control fluid
   temperature signal, engine computer adjusts a predetermined temperature control fluid
   temperature value based on the comparison of the engine oil temperature signal to the
   predetermined engine oil temperature value, the engine computer comparing the
   temperature control fluid temperature signal to the adjusted predetermined temperature
   control fluid value, and the engine computer providing signals for controlling the
   actuation of the flow control valve between its first and second states as a function of
   the comparison of the temperature control fluid temperature signal to the adjusted
   temperature control fluid temperature value.

5. A temperature control system in a liquid cooled internal combustion
   engine equipped with a radiator, the system comprising:

   (a) a first flow control valve for controlling flow of a temperature
       control fluid through a passageway which is in communication with the radiator, the
       first flow control valve having a first state for preventing said flow and a second state
       for allowing said flow;

   (b) a first sensor for measuring the temperature of the temperature
       control fluid and for providing a signal indicative thereof;

   (c) a second sensor for measuring ambient air temperature and for
       providing a signal indicative thereof;

   (d) a third sensor for measuring actual engine operation temperature
       for providing a signal indicative thereof; and

   (e) an engine computer for receiving signals from the sensors, the engine
       computer comparing the measured engine operation temperature to a preselected engine
       operation temperature, the engine computer selecting a temperature control curve for
       controlling the state of the valve based on the comparison of the measured engine
       operation temperature to the preselected engine operation temperature, the temperature
control curve being defined by a set of points having an ambient air temperature component and a temperature control fluid component, a first curve being selected when the actual engine operation temperature is at or below the preselected temperature, and a second curve being selected when the actual engine operation temperature is above the preselected temperature, the engine computer comparing the measured ambient air temperature signal and the measured temperature control fluid temperature signal to the selected curve, the engine computer producing control signals based on the comparison, and the engine computer sending the control signals to the first flow control valve to control the state of the valve.

6. A temperature control system according to claim 5 wherein the second curve is generally a shifted down version of the first curve when ambient air temperature is plotted on an x-axis and temperature control fluid is plotted on a y-axis.

7. A temperature control system according to claim 5 wherein at least a portion of the first and second curves have a generally positive slope in an area defined by a temperature control fluid temperature range from about 100 degrees Fahrenheit (37.8°C) to about 260 degrees Fahrenheit (126.7°C) and an ambient air temperature range from about 100 degrees Fahrenheit (37.8°C) to about zero degrees Fahrenheit (-17.8°C).

8. A temperature control system according to claim 5 wherein at least a portion of the first and second curves have a generally zero slope in an area where ambient air temperature is generally less than zero degrees Fahrenheit (-17.8°C).

9. A temperature control system according to claim 5 wherein the first curve is generally similar to the second curve, except for a bump-up region in the first curve in a selected range of ambient air temperatures when ambient air temperature is plotted on the x-axis and temperature control fluid is plotted on the y-axis.
10. A temperature control system according to claim 5 further comprising:
   means for storing the optimum engine operation temperature for a range of ambient air temperatures and outputting the optimum engine operation temperature for the measured ambient air temperature, wherein the preselected engine operation temperature is the optimum engine operation temperature at the current measured ambient air temperature.

11. A temperature control system according to claim 5 further comprising:
   a second flow control valve for controlling flow of the temperature control fluid through a second passageway, the second flow control valve having a first state for restricting said flow and a second state for allowing unrestricted flow,
   the engine computer sending control signals to place the second valve in the first state when the measured ambient air temperature signal and the measured temperature control fluid temperature signal define a point located above the selected curve, and sending said control signals to place the valve in the second state when the measured temperature signals define a point located below the selected curve.

12. A temperature control system according to claim 6 wherein the second curve is shifted down from the first curve by about 50 degrees Fahrenheit (27.8°C).

13. A temperature control system according to claim 9 wherein the bump-up region is from about 110 degrees Fahrenheit (43.3°C) to about 20 degrees Fahrenheit (-6.7°C).

14. A temperature control system according to claim 9 wherein the bump-up region has a maximum bump-up of about 65 degrees Fahrenheit (36.1°C) and becomes smaller as the ambient air temperature decreases.
15. A temperature control system according to claim 13 wherein the bump-up region has a maximum bump-up of about 65 degrees Fahrenheit (36.1°C) at an ambient temperature of about 85 degrees Fahrenheit (29.4°C) and becomes smaller as the ambient air temperature approaches 20 degrees Fahrenheit (-6.7°C).

16. A temperature control system in a liquid cooled internal combustion engine being equipped with a radiator, the system comprising:
   (a) a flow control valve for controlling flow of a temperature control fluid through a passageway which is in communication with the radiator, the first flow control valve having a first state for preventing said flow and a second state for allowing said flow, the valve being in the first state during warm-up or start-up;
   (b) a first sensor for measuring actual engine operation temperature;
   (c) means for comparing the measured engine operation temperature to a preselected engine operation temperature; and
   (d) an engine computer for producing control signals and sending said control signals to the flow control valve to control the state of the valve, the engine computer maintaining the valve in the first state until the actual engine operation temperature reaches the preselected engine operation temperature, regardless of the temperature of the temperature control fluid, the engine computer placing the valve in the second state when the actual engine operation temperature reaches the preselected engine operation temperature.

17. A temperature control system according to claim 16 further comprising:
   (e) a second sensor for measuring ambient air temperature; and
   (f) means for storing the optimum engine operation temperature for a range of ambient air temperatures and outputting the optimum engine operation temperature for the measured ambient air temperature, wherein the preselected engine operation temperature is the optimum engine operation temperature at the current measured ambient air temperature.
18. A temperature control system in a liquid cooled internal combustion engine equipped with a radiator, the system comprising:

   a first flow control valve for controlling flow of a temperature control fluid through a passageway, the first flow control valve having a first state for inhibiting said flow and a second state for allowing said flow;

   a first sensor for measuring actual engine operation temperature and for providing a signal indicative thereof;

   a second sensor for measuring actual ambient temperature and for providing a signal indicative thereof;

   means responsive to said actual ambient temperature signal for determining a desired engine operation temperature based on said actual ambient temperature, said desired engine operation temperature varying as a function of ambient temperature;

   means for comparing said actual engine operation temperature to said desired engine operation temperature; and

   means for controlling the state of the flow control valve between said first and second states, said flow control valve being in said first state when said actual engine operation temperature is less than said desired engine operation temperature and said flow control valve being in said second state when said actual engine operation temperature exceeds said desired engine operation temperature.

19. A temperature control system according to claim 18 further comprising a third sensor for measuring said temperature control fluid temperature and for providing a signal indicative thereof, and wherein said means for controlling the state of the flow control valve translates the flow control valve between said first and second states as a function of said sensed actual ambient temperature and said sensed temperature control fluid temperature.

20. A temperature control system according to claim 18 wherein the passageway communicates with a cylinder head and an intake manifold and wherein said flow control valve controls flow between the cylinder head and the intake manifold.
21. A temperature control system according to claim 18 wherein said flow control valve controls flow between the engine and the radiator.

22. A temperature control system according to claim 5, 16 or 18 further comprising:

- a heat exchanger in an oil pan, the heat exchanger having an inlet and an outlet;

- a conduit connected to the inlet of the heat exchanger and communicates with the passageway; and

- a water pump having an inlet connected to the radiator and the outlet of the heat exchanger, and an outlet connected to the passageway,

wherein at least one state of the flow control valve enables flow of at least a portion of the temperature control fluid to the heat exchanger.

23. A temperature control system according to claim 22 wherein the heat exchanger is a heat conductive tube.

24. A temperature control system according to claim 5, 10, 16, 17 or 18 further comprising an altitude sensor and means for adjusting the preselected engine operation temperature in accordance with the altitude.

25. A temperature control system according to claim 5, 10, 16, 17, 18 or 19 wherein the engine operation temperature is the engine oil temperature.

26. A temperature control system according to claim 5, 10, 16, 17, 18 or 19 wherein the engine operation temperature is the temperature of the engine block.

27. A temperature control system according to claim 25 wherein the engine includes an oil pan, and wherein the engine oil temperature is the oil temperature in the oil pan.
28. A temperature control system according to claim 1, 2, 3 or 4 wherein the engine also includes an engine block, and wherein the temperature sensed by the sensor is the temperature of the engine block.

29. A temperature control system according to claim 1, 2, 3, 4, 5, 11, 16, 18, or 19 wherein the flow control valve is a hydraulically controlled diaphragm valve.

30. A temperature control system according to claim 1, 2, 3, 4, 5, 11, 16, 18 or 19 wherein the flow control valve is an electronically assisted thermostat.

31. A temperature control system according to claim 30 wherein the electronically assisted thermostat includes
   
a housing;

   a valve member reciprocatable within the housing between the open state and the closed state;

   a return spring for biasing the valve member into the open state;

   a wax pellet attached to the valve member and having a solid state and a liquid state, the wax pellet maintaining the valve member in its closed state when the wax pellet is in its solid state, and the wax pellet allowing the return spring to bias the valve member into its open position when the wax pellet is in its liquid state;

   a heating element mounted within the housing and adapted to transfer heat to wax pellet, the heating element receiving an electrical transmission for producing heating of the heating element; and

   wherein the signals from the engine computer control the electrical transmission to the heating element.

32. A temperature control system according to claim 31 wherein the heating element is a heating coil looped around the wax pellet.
33. A temperature control system according to claim 31 wherein the heating element is disposed within the wax pellet.

34. A temperature control system according to claim 31 wherein the wax pellet has a melting point of approximately 220°F (104.4 °C).

35. A temperature control system according to claim 31 wherein the engine computer controls the electrical transmission so as to produce heating of the heating element when the engine oil temperature signal is greater than the predetermined engine oil temperature value.

36. A temperature control system according to claim 4 wherein the engine computer determines an amount that the engine oil temperature signal exceeds the predetermined engine oil temperature value and wherein the engine computer adjusts the predetermined temperature control fluid temperature value as a function of the amount of said excess.

37. A temperature control system according to claim 4 wherein the engine computer adjusts the predetermined temperature control fluid temperature value downward a preset amount for each one degree that the engine oil temperature signal exceeds the predetermined engine oil temperature value.

38. A temperature control system according to claim 37 wherein the preset amount of adjustment is a value within a range of between about one degree Fahrenheit (0.56 °C) and about ten degrees Fahrenheit (5.6 °C).

39. A temperature control system in a liquid cooled internal combustion engine equipped with a radiator and a water jacket, the system comprising:

- a flow control valve for controlling flow of a temperature control fluid through the water jacket, the flow control valve having a first state for inhibiting said flow and a second state for allowing said flow;
a first sensor for sensing an actual engine oil temperature and for providing a signal indicative thereof;
a second sensor for sensing an actual ambient air temperature and for providing a signal indicative thereof;
a third sensor for sensing an actual temperature control fluid temperature and for providing a signal indicative thereof;
an engine computer for receiving the actual engine oil temperature, the actual ambient air temperature and the temperature control fluid temperature, the engine computer determining a desired engine oil temperature based on ambient air temperature, the desired engine oil temperature varying as a function of the actual ambient air temperature, the engine computer comparing the actual engine oil temperature to the desired engine oil temperature for determining the temperature state of the engine, the engine computer adjusting a set of predetermined values based on the temperature state of the engine, the set of predetermined values having a temperature control fluid temperature component and an ambient air temperature component, the set of predetermined values defining a curve which determines the state of the flow control valve, the engine computer determining a desired temperature control fluid temperature by comparison of the actual ambient temperature to the adjusted set of predetermined values, the engine computer comparing the actual temperature control fluid temperature to the desired temperature control fluid temperature and controlling the actuation of the flow control valve between its first and second states depending on the comparison of the actual temperature control fluid temperature to the desired temperature control fluid temperature, the flow control valve being in the first state when the actual temperature control fluid temperature is less than the desired temperature control fluid temperature, and the flow control valve being in the second state when the actual temperature control fluid temperature is greater than the desired temperature control fluid temperature.

40. A temperature control system according to claim 39 wherein the engine computer determines an engine load condition based on a comparison of the actual engine oil temperature to the desired engine oil temperature, and wherein the engine
computer adjusts the temperature control fluid temperature component of the set of predetermined values in accordance with the load condition.

41. A temperature control system according to claim 39 wherein the engine computer determines an amount that the actual engine oil temperature exceeds the desired engine oil temperature and wherein the engine computer adjusts the temperature control fluid temperature component of the set of predetermined values as a function of the amount of said excess.

42. A temperature control system according to claim 39 wherein the engine computer adjusts the temperature control fluid temperature component of the set of predetermined values downward a preset amount for each one degree that the actual engine oil temperature exceeds the desired engine oil temperature.

43. A temperature control system according to claim 39 wherein the engine computer adjusts the temperature control fluid temperature component of the set of predetermined values downward a preset amount for each three degrees Fahrenheit that the actual engine oil temperature exceeds the desired engine oil temperature.

44. A temperature control system according to claim 39 wherein the engine computer adjusts the temperature control fluid temperature component of the set of predetermined values downward a preset amount for each five degrees Fahrenheit that the actual engine oil temperature exceeds the desired engine oil temperature.

45. A temperature control system according to claim 39 wherein the engine computer determines a rate of change of the actual engine oil temperature and wherein the engine computer adjusts the temperature control fluid temperature component of the set of predetermined values as a function of the rate of change.

46. A temperature control system according to claim 39 wherein the engine computer determines an adjustment factor for adjusting the temperature control
fluid temperature component of the set of predetermined values, the adjustment factor varying as a function of ambient air temperature, and wherein the engine computer adjusts the temperature control fluid temperature component of the set of predetermined values according to the adjustment factor.

47. A temperature control system according to claim 39 wherein the engine includes an intake manifold and wherein the engine computer receives signals from the intake manifold indicative of an intake manifold vacuum pressure, and wherein the engine computer determines an engine load condition based on the intake manifold vacuum pressure and adjusts the temperature control fluid temperature component of the set of predetermined values in accordance with the load condition.

48. A temperature control system according to claim 42 wherein the preset amount of adjustment is a value within a range of between about one degree Fahrenheit (0.56°C) and about ten degrees Fahrenheit (5.6°C).

49. A temperature control system according to claim 45 wherein the adjusting of the temperature control fluid temperature component of the set of predetermined values varies linearly with the rate of change of the actual engine oil temperature.

50. A temperature control system according to claim 45 wherein the adjusting of the temperature control fluid temperature component of the set of predetermined values varies nonlinearly with the rate of change of the actual engine oil temperature.

51. A temperature control system according to claim 46 wherein the adjustment factor varies linearly with ambient air temperature.

52. A temperature control system according to claim 46 wherein the adjustment factor varies nonlinearly with ambient air temperature.
53. A temperature control system according to claim 47 wherein the engine load condition is a high load condition when the intake manifold vacuum pressure is less than about 4 inches Hg (13.55 kPa) and wherein the engine computer adjusts the temperature control fluid temperature component of the set of predetermined values downward a first preset amount.

54. A temperature control system according to claim 47 wherein the engine load condition is an extremely high load condition when the intake manifold vacuum pressure is less than about 2 inches Hg (6.77 kPa) and wherein the engine computer adjusts the temperature control fluid temperature component of the set of predetermined values downward a second preset amount.

55. A temperature control system according to claim 48 wherein the preset amount of adjustment is about three degrees Fahrenheit (1.67°C).

56. A temperature control system according to claim 55 wherein the preset amount of adjustment is about two degrees Fahrenheit (1.22°C).

57. A temperature control system according to claim 56 wherein the preset amount of adjustment is one degree Fahrenheit (0.56°C).

58. A temperature control system in a liquid cooled internal combustion engine equipped with a radiator and a water jacket, the system comprising:

a flow control valve for controlling flow of a temperature control fluid through the water jacket, the flow control valve having a first state for inhibiting said flow and a second state for allowing said flow;

a first sensor for sensing an actual engine oil temperature and for providing a signal indicative thereof;

a second sensor for sensing an actual ambient air temperature and for providing a signal indicative thereof;
a third sensor for sensing an actual temperature control fluid temperature and for providing a signal indicative thereof;

means responsive to the actual ambient temperature signal for determining a desired engine oil temperature based on the actual ambient temperature, the desired engine oil temperature varying as a function of the actual ambient temperature;

means for comparing the actual engine oil temperature to the desired engine oil temperature;

means for determining an engine load condition based on the comparison of the actual engine oil temperature to the desired engine oil temperature;

means for determining a desired temperature control fluid temperature;

means for determining an adjustment factor as a function of the engine load condition;

means for adjusting the desired temperature control fluid temperature in accordance with the determined adjustment factor;

means for comparing the actual temperature control fluid temperature to the adjusted desired temperature control fluid temperature for determining a desired state of the flow control valve; and

means for actuating the flow control valve into the desired state.

59. A method for controlling the state of a flow control valve in an internal combustion engine, the flow control valve controlling flow of temperature control fluid through a passageway and having a first state for inhibiting the flow of temperature control fluid through the passageway and a second state for allowing the flow of temperature control fluid through the passageway, the method comprising the steps of:

receiving a temperature signal indicative of the engine oil temperature;

comparing the engine oil temperature signal to a predetermined engine oil temperature value; and
actuating the flow control valve between its first and second states based on the comparison of the engine oil temperature signal to the predetermined engine oil temperature value.

60. A method according to claim 59 further comprising the step of providing signals for actuating the flow control valve.

61. A method for controlling the temperature state of an internal combustion engine, the engine including a flow control valve for controlling flow of temperature control fluid between a radiator and a passageway in the engine, the valve having a first state for inhibiting the flow of temperature control fluid between the radiator and the passageway and a second state for allowing the flow of temperature control fluid between the radiator and the passageway, the flow of temperature control fluid between the radiator and the passageway providing cooling of the engine, the method comprising the steps of:

receiving a temperature signal indicative of the engine oil temperature;

and

maintaining the temperature signal substantially at a predetermined temperature value by actuating the flow control valve into its second state when the temperature signal is greater than the predetermined temperature value and by actuating the flow control valve into its first state when the temperature signal is less than the predetermined temperature value.

62. A method for controlling the state of a flow control valve in an internal combustion engine equipped with a radiator and an engine computer, the flow control valve controlling flow of temperature control fluid, the method comprising the steps of:

measuring the temperature of the temperature control fluid with a first temperature sensor;

measuring the ambient air temperature with a second temperature sensor;
measuring the actual engine operation temperature with a third
temperature sensor;
comparing the actual engine operation temperature to a preselected engine
operation temperature;
5 defining a first curve having a temperature control fluid temperature
component and an ambient air temperature component;
defining a second curve having a temperature control fluid temperature
component and an ambient air temperature component;
selecting either the first or second curve to control the state of the valve.
the first curve being selected when the actual engine operation temperature is at or below
the preselected temperature, the second curve being selected when the actual engine
operation temperature is above the preselected temperature;
locating a point defined by the measured ambient air temperature and
the measured temperature of the temperature control fluid on the selected curve; and
sending control signals to the valve to actuate the valve into either a first
state for preventing said flow when the point is located below the selected curve, or a
second state for allowing said flow when point is located above the selected curve.
63. A method according to claim 62 wherein the second curve is
generally a shifted down version of the first curve when ambient air temperature is
plotted on the x-axis and temperature control fluid is plotted on the y-axis.

64. A method according to claim 62 wherein at least a portion of the
first and second curves have a generally positive slope at least a portion of which is in
an area defined by a temperature control fluid temperature range from about 100 degrees
Fahrenheit (37.8°C) to about 260 degrees Fahrenheit (126.7°C) and an ambient air
temperature range from about 100 degrees Fahrenheit (37.8°C) to about zero degrees
Fahrenheit (-17.8°C).
65. A method according to claim 62 wherein at least a portion of the first and second curves have a generally zero slope a portion of which is in an area where ambient air temperature is generally less than zero degrees Fahrenheit (−17.8°C).

66. A method according to claim 63 wherein the second curve is shifted down from the first curve by about 50 degrees Fahrenheit (27.8°C).

67. A method for controlling the state of a flow control valve in an internal combustion engine equipped with a radiator and an engine computer, the flow control valve controlling flow of temperature control fluid, the method comprising the steps of:

- measuring the temperature \( t_1 \) of the temperature control fluid with a first temperature sensor and sending \( t_1 \) to the engine computer;
- measuring the ambient air temperature \( t_2 \) with a second temperature sensor and sending \( t_2 \) to the engine computer;
- measuring the actual engine operation temperature with a third temperature sensor;
- comparing the actual engine operation temperature to a preselected engine operation temperature;
- defining a first mathematical function of \( t_1 = f(t_2) \) which forms a first two-dimensional curve on an orthogonal coordinate system having axes \( t_1 \) and \( t_2 \), the first curve dividing the coordinate system into two regions, one on either side of the first curve;
- defining a second mathematical function of \( t_1 = f(t_2) \) which forms a second two-dimensional curve on an orthogonal coordinate system having axes \( t_1 \) and \( t_2 \), the second curve dividing the coordinate system into two regions, one on either side of the second curve;
- selecting either the first or second curve to control the state of the valve, the first curve being selected during engine warm-up or start-up, the second curve being selected when the actual engine operation temperature reaches the preselected temperature;
determining in the engine computer which region of the coordinate system of the selected curve the measured temperatures t1 and t2 lie in; and

sending control signals from the engine computer to the valve to actuate the valve into either a first state for preventing said flow when coordinate pairs of t1 and t2 lie in the first region of the coordinate system of the selected curve, or a second state for allowing said flow when coordinate pairs of t1 and t2 lie in the second region of the coordinate system of the selected curve.

68. A method according to claim 67 wherein the first curve is generally similar to the second curve, except for a bump-up region in the first curve in a selected range of ambient air temperatures when ambient air temperature is plotted on the x-axis and temperature control fluid is plotted on the y-axis.

69. A method according to claim 68 wherein the bump-up region is from about 110 degrees Fahrenheit (43.3°C) to about 20 degrees Fahrenheit (-6.7°C).

70. A method according to claim 68 wherein the bump-up region has a maximum bump-up of about 65 degrees Fahrenheit (36.1°C) and becomes smaller as the ambient air temperature decreases.

71. A method according to claim 69 wherein the bump-up region has a maximum bump-up of about 65 degrees Fahrenheit (36.1°C) at an ambient temperature of about 85 degrees Fahrenheit (29.4°C) and becomes smaller as the ambient air temperature approaches 20 degrees Fahrenheit (-6.7°C).

72. A method for controlling the state of a flow control valve in an internal combustion engine, the engine including a radiator and a water jacket, the flow control valve controlling flow of temperature control fluid between the water jacket and the radiator, the valve having a closed state for preventing flow of the temperature control fluid, the method comprising the steps of:
measuring the actual engine operation temperature with a first temperature sensor;

comparing the actual engine operation temperature to a preselected engine operation temperature; and

maintaining the valve in the closed state until the actual engine operation temperature reaches the preselected engine operation temperature, regardless of the temperature of the temperature control fluid, the engine computer causing the valve to actuate into a second state when the actual engine operation temperature reaches the preselected engine operation temperature.

A method according to claim 72 further comprising the steps of:

storing the optimum engine operation temperature for a range of ambient air temperatures; and

measuring the ambient air temperature with a second temperature sensor and determining the optimum engine operation temperature for the measured ambient air temperature, wherein the preselected engine operation temperature is the optimum engine operation temperature at the current measured ambient air temperature.

A method for controlling the state of a flow control valve in an internal combustion engine equipped with a radiator and an oil pan, the flow control valve controlling flow of temperature control fluid, the method comprising the steps of:

measuring an engine operation temperature;

measuring an ambient air temperature;

determining a threshold engine operation temperature value for the sensed ambient temperature, said threshold engine operation temperature value varying as a function of the ambient air temperature;

comparing the engine operation temperature with the threshold engine operation temperature value to determine the temperature state of the engine;

determining a desired valve position based on the temperature state of the engine;

actuating the valve so as to place it in said desired valve position.
75. A method according to claim 74 wherein said desired valve position inhibits fluid flow to the radiator and permits flow to the oil pan.

76. A method according to claim 74 wherein said desired valve position permits flow to the intake manifold.

77. A method according to claim 74 wherein said first temperature is engine oil temperature.

78. A method according to claim 74 wherein the step of determining the desired valve position comprising the steps of:

measuring a temperature of the temperature control fluid;

determining a desired temperature control fluid temperature value for the sensed ambient temperature and based on the temperature state of the engine, the desired temperature control fluid temperature value varying as a function of the ambient air temperature and the temperature state of the engine; and

comparing the measured temperature control fluid temperature to the desired temperature control fluid temperature value to determine the desired valve position.

79. A method for controlling the flow of temperature control fluid in an internal combustion engine equipped with a radiator, a water jacket in an engine block, a water jacket in a cylinder head and a water jacket in an oil pan, the method comprising the steps of:

measuring a first temperature which is indicative of the engine temperature;

measuring an ambient air temperature;

determining a threshold engine temperature value for said sensed ambient temperature, said threshold engine temperature value varying as a function of said ambient air temperature;
comparing said first temperature with the threshold engine temperature value;
permitting flow of the temperature control fluid through the cylinder head water jacket and the oil pan water jacket and preventing flow through the radiator when the first temperature is less than the threshold engine temperature value, whereby heat from the cylinder head is transferred to oil pan by the temperature control fluid; and
permitting flow of the temperature control fluid through the engine block water jacket and the cylinder head water jacket when the first temperature is greater than the threshold engine temperature value.

80. A method according to claim 79 wherein the engine furthermore includes a water jacket in an intake manifold, the method further comprising permitting flow of the temperature control fluid through the intake manifold when the first temperature is less than the threshold engine temperature value.

81. A method according to claim 79 wherein the first temperature is the temperature of the temperature control fluid and wherein the threshold engine temperature value is a threshold value for the temperature control fluid.

82. A method according to claim 62 or 67 further comprising the steps of:

storing the optimum engine operation temperature for a range of ambient air temperatures; and
employing the ambient air temperature measurement to determine the optimum engine operation temperature for the measured ambient air temperature, wherein the preselected engine operation temperature is the optimum engine operation temperature at the current measured ambient air temperature.

83. A method according to claim 62, 67, 72, 73 or 82 wherein the engine operation temperature is the engine oil temperature.
84. A method according to claim 83 wherein the engine oil temperature is the oil temperature in the oil pan.

85. A method according to claim 62, 67, 72, 74, 78 or 79 further comprising the steps:

measuring the altitude with an altitude sensor; and

adjusting the preselected engine operation temperature in accordance with the altitude.

86. A method according to claim 62, 67, 72, 74 or 79 wherein the engine is further equipped with a heat exchanger in an oil pan, the heat exchanger having an inlet and an outlet; a water jacket having an outlet connected to the inlet of the heat exchanger; and a water pump having an inlet connected to the outlet of the radiator and the outlet of the heat exchanger, and an outlet connected to the inlet of the water jacket, the method further comprising the step of channeling at least a portion of the temperature control fluid flow from the water jacket through the heat exchanger.

87. A method for controlling the state of a flow control valve in an internal combustion engine, the flow control valve controlling flow of temperature control fluid through a passageway and having a first state for inhibiting the flow of temperature control fluid through the passageway and a second state for allowing the flow of temperature control fluid through the passageway, the method comprising the steps of:

receiving a temperature signal indicative of the engine oil temperature;

receiving a temperature control fluid temperature signal indicative of the temperature control fluid temperature;

comparing the engine oil temperature signal to a predetermined engine oil temperature value; and
adjusting a predetermined temperature control fluid temperature value based on the comparison of the engine oil temperature signal to the predetermined engine oil temperature value;

comparing the temperature control fluid temperature signal to the adjusted temperature control fluid temperature value; and

actuating the flow control valve between its first and second states based on the comparison of the temperature control fluid temperature signal to the adjusted temperature control fluid temperature value.

88. A method according to claim 87 further comprising the steps of sensing a temperature indicative of the engine oil temperature and providing the engine oil temperature signal indicative thereof, and sensing a temperature control fluid temperature and providing the temperature control fluid temperature signal indicative thereof.

89. A method according to claim 87 wherein the adjusting of the temperature control fluid temperature comprises the steps of:

determining the amount that the engine oil temperature signal exceeds the predetermined engine oil temperature value;

determining an adjustment factor for adjusting the predetermined temperature control fluid temperature value based on the amount of said excess; and

combining the adjustment factor and the predetermined temperature control fluid temperature value to form the adjusted temperature control fluid temperature value.

90. A method according to claim 59, 61, 62, 67, 72, 74 or 87 wherein the flow control valve is an electronically assisted thermostat and wherein the step of actuating the flow control valve involves sending an electrical transmission to a heating element so as to produce heating of the element, melting a wax pellet by exposing it to the heated coil, the melting of the wax producing actuation of the valve.
91. A method for controlling the state of a flow control valve in an internal combustion engine, the flow control valve controlling flow of temperature control fluid through a passageway and having a first state for inhibiting the flow of temperature control fluid through the passageway and a second state for permitting the flow of temperature control fluid through the passageway, the method comprising the steps of:

- measuring an actual engine oil temperature;
- measuring an actual ambient air temperature;
- measuring an actual temperature control fluid temperature;
- determining a desired engine oil temperature value for the actual ambient air temperature, said desired engine oil temperature value varying as a function of the ambient air temperature;
- comparing the actual engine oil temperature to the desired engine oil temperature value;
- determining a desired temperature control fluid temperature for the actual ambient air temperature, the desired temperature control fluid temperature varying as a function of the ambient air temperature;
- adjusting the desired temperature control fluid temperature based on the comparison of the actual engine oil temperature to the desired engine oil temperature value;
- comparing the actual temperature control fluid temperature to the adjusted desired temperature control fluid temperature; and
- actuating the flow control valve so as to place said valve in its first state when the actual temperature control fluid temperature is less than the adjusted desired temperature control fluid temperature, and actuating the valve to place it in its second state when the actual temperature control fluid temperature is greater than the adjusted desired temperature control fluid temperature.

92. A method according to claim 91 wherein said first state inhibits fluid flow to the radiator.
93. A method according to claim 91 wherein said first state permits flow to the intake manifold.

94. A method according to claim 91 wherein the adjusting of the temperature control fluid temperature comprises the steps of:
   determining the amount that the actual engine oil temperature exceeds the desired engine oil temperature;
   determining an adjustment factor for adjusting the desired temperature control fluid temperature based on the amount of said excess; and
   combining the adjustment factor and the desired temperature control fluid temperature to form the adjusted desired temperature control fluid temperature.

95. A method according to claim 91 wherein the adjusting of the temperature control fluid temperature component comprises the steps of:
   determining a rate of change of the actual engine oil temperature with respect to the desired engine oil temperature;
   determining an adjustment factor for adjusting the desired temperature control fluid temperature based on the rate of change of the actual oil temperature; and
   combining the adjustment factor and the desired temperature control fluid temperature to form the adjusted desired temperature control fluid temperature.

96. A method according to claim 91 wherein the adjusting of the temperature control fluid temperature component comprises the step of:
   determining an adjustment factor for adjusting the desired temperature control fluid temperature based on the actual ambient air temperature, the adjustment factor varying as a function of at least ambient air temperature; and
   combining the adjustment factor and the desired temperature control fluid temperature to form the adjusted desired temperature control fluid temperature.

97. A method for controlling the state of a flow control valve in an internal combustion engine, the flow control valve controlling flow of temperature
control fluid through a passageway and having a first state for inhibiting the flow of
temperature control fluid through the passageway and a second state for permitting the
flow of temperature control fluid through the passageway, the method comprising the
steps of:

5 measuring an actual engine oil temperature;
measuring an actual ambient air temperature;
measuring an actual temperature control fluid temperature;
determining a desired engine oil temperature value for the actual ambient
temperature, said desired engine oil temperature value varying as a function of the
ambient air temperature;
comparing the actual engine oil temperature to the desired engine oil
temperature value;
determining an adjustment factor based on the comparison of the actual
engine oil temperature to the desired engine oil temperature;

15 combining the adjustment factor with at least one temperature control
fluid temperature component of a set of predetermined values having temperature control
fluid temperature component and an ambient air temperature component, the combination
forming an adjusted temperature control fluid temperature component;
determining a desired state of the flow control valve by comparing the
actual temperature control fluid temperature to the adjusted temperature control fluid
temperature component and comparing the actual ambient air temperature to the ambient
air temperature component of the set of predetermined values; and
actuating the valve so as to place it in the desired state.

20 98. A method according to claim 97 wherein the set of predetermined
values defines a curve, at least a portion of the curve having a non-zero slope.

99. A method according to claim 97 wherein the adjustment factor varies
as a function of ambient air temperature.
100. A method according to claim 97 wherein the determination of the adjustment factor further comprises the steps of:

determining the amount that the actual engine oil temperature exceeds the desired engine oil temperature; and

determining an adjustment factor based on the amount of excess.

101. A method according to claim 97 wherein the determination of the adjustment factor further comprises the steps of:

determining a rate of change of the actual engine oil temperature with respect to the desired engine oil temperature; and

determining an adjustment factor based on the rate of change of the actual oil temperature.

102. A method for controlling the flow of temperature control fluid in an internal combustion engine comprising the steps of:

measuring an actual engine oil temperature;

measuring an actual ambient air temperature;

measuring an actual temperature control fluid temperature;

determining a desired engine oil temperature value for the actual ambient temperature, the desired engine oil temperature value varying as a function of the ambient air temperature;

comparing the actual engine oil temperature to the desired engine oil temperature value;

providing a temperature control curve defining the flow of temperature control fluid through the internal combustion engine, the temperature control curve having temperature control fluid temperature components and ambient air temperature components;

adjusting the temperature control curve based on the comparison of the actual engine oil temperature to the desired engine oil temperature value;

comparing the actual temperature control fluid temperature and the actual ambient air temperature to the adjusted temperature control curve; and
controlling the flow of temperature control fluid based on the comparison of the actual temperature control fluid temperature and the actual ambient temperature to the adjusted temperature control curve.

* Special categories of cited documents:

  "A" document defining the general state of the art which is not considered to be of particular relevance.

  "E" earlier document but published on or after the international filing date.

  "L" document which may throw doubts on priority claim(s) or which is cited to establish the publication date of another citation or other special reason (as specified).

  "O" document referring to an oral disclosure, use, exhibition or other means.

  "P" document published prior to the international filing date but later than the priority date claimed.

  "T" later document published after the international filing date or priority date and not in conflict with the application but cited to understand the principle or theory underlying the invention.

  "X" document of particular relevance; the claimed invention cannot be considered to involve an inventive step if the prior art contained in this document is referred to and it was not considered by the examiner.

  "Y" document of particular relevance; the claimed invention cannot be considered to involve an inventive step if the prior art contained in this document is referred to and it is not mentioned in this report.

  "A" document member of the same patent family.

Date of the actual completion of the international search

3 June 1996

Date of mailing of the international search report

13.06.96

Name and mailing address of the ISA

European Patent Office, P.B. 5818 Patentslands 2
NL-2280 HVB Emmerik
Tel. (+31-70) 340-2040, Telex 31 651 epo nl
Fax (+31-70) 340-3016

Authorized officer

Kooijman, F

Form PCT/ISA 318 (second sheet) (July 1992)
